MANAGERIAL ASSESSMENT
An International Comparison

BERNARD M. BASS and PHILIP C. BURGER

This monumental international survey of the attitudes and behavior of corporate executives in 12 nations and regions documents which managerial traits lead to success in different countries. "Far more comprehensive in scope ... than anything previously written on the subject." —Victor Vroom, Yale University

224 pages *ISBN 0-02-901960-5* *$15.95*

BETWEEN PUBLIC AND PRIVATE
Lost Boundaries of the Self

JOSEPH BENSMAN and ROBERT LILIENFELD

The authors integrate Freudian, neo-Freudian, and symbolic interactionist theories with theories or bureaucracy, mass communication, class, and politics to shed new light on the concepts of public and private as roles that mediate the relation between individual psychological needs and societal and cultural demands.

cloth 196 pages *ISBN 0-02-902690-3* *$13.95*
paper 196 pages *ISBN 0-02-902680-6* *$7.95*

INTERGROUP PROCESSES
A Micro-Macro Perspective

HUBERT M. BLALOCK and PAUL H. WILKEN

The authors provide a much needed link between micro-level theories of the motives, behavior, and interactions of individuals and macro-level theories concerned with complex organizations, nation-states, social classes and racial groups. And, they demonstrate that macro-level theories must take account of behavioral assumptions.

540 pages *ISBN 0-02-903620-8* *$22.9*

HUMAN SOCIOBIOLOGY
A Holistic Approach

DANIEL G. FREEDMAN

"Freedman is one of the first social scientists to combine a professional knowledge of human behavior with a solid understanding of evolutionary theory. *Human Sociobiology* is an excellent work, the first of its kind." —Edward O. Wilson, author of *Sociobiology: The New Synthesis*

242 pages *ISBN 0-02-910660-5* *$12.9*

BIAS IN MENTAL TESTING

ARTHUR R. JENSEN

In the most detailed and thoroughly researched study ever published on this topic, Arthur Jensen examines psychometric methods for objectively detecting bias in mental testing and challenges the claim that standardized tests are culturally biased against native-born minorities.

800 pages *ISBN 0-02-916430-3* *$29.9*

UNDERSTANDING HUMAN VALUES
Individual and Societal

Edited by MILTON ROKEACH

Elaborating on the ideas put forth in his highly acclaimed work, *The Nature of Human Values*, Rokeach brings together recent contributions that advance theoretical, methodological, and empirical knowledge of the role human values play in everyday life.

288 pages *ISBN 0-02-926760-9* *$14.95*

THE NEW EDITION OF THE ONE THEY ALL FOLLOWED - READY TO TAKE SECOND-SEMESTER LEADERSHIP

SOCIAL PSYCHOLOGY AND MODERN LIFE
Second Edition

Patricia Niles Middlebrook, Central Connecticut State College

SOCIAL PSYCHOLOGY AND MODERN LIFE was the first introductory text to successfully combine rigorous, research-oriented scholarship with consistently engaging material that reflected students' deepest concerns, fascinated them, and made them think. More than any other, it was the text that secured the place of social psychology as one of the richest and most exciting courses in the college curriculum. The first edition has had a long and renowned life of leadership.

Succeeding texts imitated—but never equalled—its groundbreaking achievement. And now, the one they all followed is ready to take the lead again, in a stunning page-by-page revision that speaks directly to today's college generation with:

- Expert collaborating authors, including Phillip Zimbardo, Robert Sommer, Marvin Shaw, Irene Frieze, Craig Haney, Terry Amabile, and William De Jong, all contributing to chapters in their areas of expertise
- Four important new chapters: "The Environment and Human Behavior," "Being Male and Female," "Social Psychology and Criminal Law," "Loneliness"
- Exhaustive updating and new material throughout, including coverage of learned helplessness, objective self-awareness, the influence of sex roles on sexual behavior, the "Vietnam Syndrome," television and aggression, marriage and cohabitation, battered wives, and the Moonies
- Lavish updated graphics program
- More concise text
- One of the most comprehensive Instructor's Manuals published

Alfred A. Knopf/December 1979/672 pages hardbound/Order Codes: 31248, 32316 (I.M.)

NEW FOR 1980

ANNOUNCING!

PsycSCAN™ CLINICAL PSYCHOLOGY

PsycSCAN™ DEVELOPMENTAL PSYCHOLOGY

Two new abstract journals each with over 1,500 full abstracts per year from relevant, selected journals — APA and non-APA — in the fields of clinical and developmental psychology. These new publications are the results of more than three years of study and analysis of the information needs of APA members.

The unique scanning format of PsycSCAN allows the reader to quickly review the specially set title, index terms, abstract, and citation for each entry.

Keep current with the ongoing literature in these important fields in psychology. Plan to order one or both PsycSCAN journals when you complete your 1980 dues statement.

Each PsycSCAN journal is:

- $8 per year for APA members ($10 for nonmembers)
- Quarterly, starting in early 1980
- Available for easy check-off ordering on the 1980 dues statement

PsycSCAN™ is produced by PsycINFO™, a service of the American Psychological Association 1200 17th Street, NW Washington, DC 20036

DORSEY Outshadows the Competition

UNDERSTANDING SOCIAL PSYCHOLOGY

Revised Edition

By **Stephen Worchel,** University of Virginia and **Joel Cooper,** Princeton University

This text presents both traditional and contemporary experimental research and theory with the emphasis on the active areas of research. Experimental research is placed in the context of "critical incidents" from the real world or literature to help the student understand these events.

The text begins with the reaction of individuals in the formation of attitudes, change of attitudes, and the attribution of characteristics to self and others. It then moves toward a consideration of the individual in a more macroscopic environment. **Teacher's Manual** and **Student Workbook.** 1979

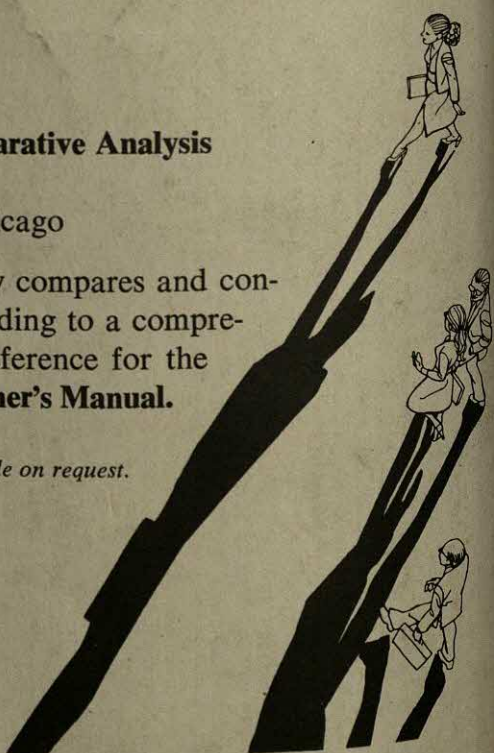
Coming in 1980

PERSONALITY THEORIES: A Comparative Analysis

Fourth Edition

By **Salvatore R. Maddi,** University of Chicago

This basic text for courses in personality compares and contrasts many theoretical viewpoints according to a comprehensive, consistent, original frame of reference for the personality field. **Teacher's Manual.**



Examination copies for adoption consideration available on request. Please indicate course title and text presently used.

The Journal of Personality and Social Psychology publishes original reports of research, methodology, theory, criticism, and literature review in the fields of personality and social psychology of normal processes and populations. Submitted manuscripts should delineate an important question and provide a clear answer to it. In the case of research reports, this will often require demonstration that the reported results are generalizable beyond a single research setting. Consult the editorial in the January 1976 issue (Vol. 33, pp. 1–7) for a detailed statement of policies and instructions to authors.

Manuscripts: Submit manuscripts in quadruplicate, prepared according to the *Publication Manual of the American Psychological Association* (2nd ed.). Copies should be highly legible and will not be returned to authors unless they are original typewritten copies. Mail manuscripts according to instructions on p. 1439 of the August issue.

Required supplementary information: Manuscripts cannot be reviewed for publication unless the author provides supplementary information in the following categories: (a) a cover letter that indicates the relation (or the lack of relation) of the submitted manuscript to other papers by the same author(s) that are currently submitted, in press, or recently published; (b) one copy of each such related paper; (c) one copy of a statement of the procedures of the research reported in the submitted manuscript in sufficient detail to serve as a guide for conduct of an exact replication; and (d) one copy of the summary tables (e.g., correlation tables, analysis of variance summaries) for the *major* analyses reported. If it appears that the supplementary materials in categories (c) or (d) might be bulky, the author should exercise judgment and restraint in selecting what to send. It is not necessary to send supplementary material that repeats verbatim manuscript content.

After a manuscript is accepted, authors will be expected to provide assurance that their data are available in unanalyzed form for reanalyses by other investigators and that their research procedures were consistent with the American Psychological Association's published principles of research ethics except insofar as may be detailed otherwise in the manuscript.

Copyright and Permission: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permission is normally granted contingent upon like permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of $10 per page, table, or figure. Abstracting is permitted with credit to the source. Permissions and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use their own material commercially. Permission and fees are waived for the photocopying of isolated articles for nonprofit classroom or library reserve use by instructors and educational institutions. Libraries are permitted to photocopy beyond the limits of U.S. copyright law: (1) those post-1977 articles with a code at the bottom of the first page, provided the per-copy fee indicated in the code is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301; (2) pre-1978 articles, provided that the per-copy fee stated in the Publishers' Fee List is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301. Address requests for reprint permission to the Permissions Office, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rate for 1979: $60 domestic, $64 foreign, $6 single issue. APA member rate: $20. Write to Subscription Section, APA.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes. Journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Published monthly in one volume per year by the American Psychological Association, Inc., 1400 North Uhle Street, Arlington, Virginia 22201. Printed in the U.S.A. Second-class postage paid at Arlington, Va., and at additional mailing offices.

Coalition Bargaining in Four Games That Include a Veto Player

J. Keith Murnighan and Eugene Szwajkowski
Organizational Behavior Group
Department of Business Administration
University of Illinois at Urbana-Champaign

This study tested the predictions of three models of coalition behavior in four different games, each including a veto player. Participants were master's students who played each of the four games, rotating among the five player positions between games. The games were played under one of three time pressure/default conditions: (a) no time pressure; (b) a condition such that the constant payoff to coalitions was lost if an agreement was not reached in three attempts; and (c) a condition such that the payoff for no agreement was fixed at 60 points for the veto player and 10 for the other players. The veto players' payoffs varied over games and tended to increase as play continued, at times approaching the entire payoff. Thus, the weighted probability and Roth–Shapley models were not supported; the core received some support. The default conditions had little effect. The discussion focuses on the likelihood of socially beneficial behavior in competitively motivating situations.

Gamson (1961) defined full-fledged coalition situations as those where more than two parties must make a decision, where the actors' preferences differ, and where no actor is a dictator (i.e., one who can impose a decision with no support from other parties) or veto player (i.e., one who must be included in every coalition). Most coalition research (Murnighan, 1978a) has focused on interactions that meet these requirements. However, a number of "real world" coalition situations include veto players: The oil producing countries have formed a cartel (the Organization of Petroleum Exporting Countries, or OPEC) that must be included in almost all major oil exchanges. Company presidents often must be included in all significant organizational decisions. And the members of the security council of the United Nations all hold veto power over the council's resolutions. Recently, research has also investigated coalition situations that include a veto player (e.g., Murnighan & Roth, 1977, 1978). The present study investigated four different veto games in conjunction with three time pressure/aspiration level conditions, to test both game-

The authors gratefully acknowledge the considerable assistance provided by three reviewers.

Eugene Szwajkowski is now at the University of Illinois at Chicago Circle.

Requests for reprints should be sent to J. Keith Murnighan, Department of Business Administration, 104 Commerce West, University of Illinois, Urbana, Illinois 61801.

Table 1
The Games, the Minimum Winning Coalitions, and the Models' Predictions for the Players' Mean Payoffs (Over All Trials)

Game	Minimum winning coalition	Models' predictions		
		Weighted probability	Core	Roth–Shapley
20(17–6–5–4–3)	AB, AC, AD, AE	80–5[a]	100–0[a,b]	80–5[a]
38(27–13–12–6–5)	AB, AC, ADE	71–11–11–3–3	100–0[a,b]	70–12–12–3–3
30(21–10–7–5–4)	AB, ACD, ACE, ADE	62–11–9–9–9	100–0[a,b]	65–15–7–7–7
28(17–8–7–6–5)	ABC, ABD, ABE, ACD, ACE, ADE	50–12.5[a]	100–0[a,b]	60–10[a]

[a] Payoff predictions that are not listed with an entry for each of the five players indicate that players B, C, D, and E are predicted to have equal payoffs.
[b] The figures listed for the core's prediction are the limits that payoffs are predicted to approach. In sequential games like those in this study, less extreme payoffs that continuously approach this limit can be taken as support for the model.

theoretic and social psychological models of coalition behavior and to establish a more general data base for veto games.

One impetus for this study is the research by Michener, Fleishman, and Vaske (1976) that investigated eight veto and eight nonveto games. The eight veto games in the study included the same set of minimum winning coalitions (i.e., those that will no longer be winning if one player is left out of the coalition). For instance, in the 14(9–6–3–2) game, where 14 refers to the number of votes needed to form a winning coalition and the numbers within the parentheses refer to the votes assigned to players designated A, B, C, and D, respectively, five different coalitions (AB, ABC, ABD, ACD, and ABCD) are winning. Only AB and ACD, however, are minimal winning. Each of the eight veto games in the Michener et al. study used this set of winning and minimum winning coalitions, with different resource distributions.

In an attempt to extend these results, the present study investigated four different five-person games that varied not only the players' resources (votes) but also the games' underlying structures (i.e., the sets of minimum winning coalitions; see Table 1). Notice that in the 20(17–6–5–4–3) game the veto player can form a winning coalition with any one of the other four players. In the 28(17–8–7–6–5) game, the opposite extreme in this set, the veto player needs two other players to form a winning coalition. The other two games fall between these two, allowing the veto player to form either one or two two-player winning coalitions. Three models of coalition behavior—the weighted probability model (Komorita, 1974), the core (Luce & Raiffa, 1957), and the Roth–Shapley value (Roth, 1977a,b; Shapley, 1953)—all make different predictions for these four games.[1] This study, then, allows for theoretical tests of three models by using four veto games that vary in their underlying structure.

Prior to discussing the other major independent variable, the time pressure/aspiration level conditions, each of the three models to be tested here will be briefly summarized, using the 30(21–10–7–5–4) game as an example.

The Weighted Probability Model

The basic assumption underlying the weighted probability model (Komorita, 1974) is that because of the logistic problem of communicating offers and counteroffers, players will attempt to form small rather than large coalitions. As the number of potential coalition members increases, the severity of the problem of achieving both reciprocity and unanimous agreement on the terms of the

[1] Other models, including Gamson's (1961) minimum resource and Komorita and Chertkoff's (1973) bargaining theories might also be tested in this study. These two models, however, either explicitly limit themselves to nonveto games or are not particularly amenable to veto games (Murnighan, 1978a) and therefore would not be appropriately tested here.

offer also increases. In addition, the number of potential defectors from the coalition increases with its size; hence, a large coalition is not only less desirable but may also be more difficult to maintain.

The weighted probability model assumes that an individual's share of the prize should be a function of the *number* and *size* of alternative minimum winning coalitions available to him or her. In the 30(21–10–7–5–4) game, Player A has four alternatives (AB, ACD, ACE, and ADE), including one two-person coalition. Player B has only one alternative (AB). Players C, D, and E each have two alternatives, both being three-person coalitions. The present form of the model assigns twice as much of an "advantage" to two-person opportunities as it does to three-person opportunities and predicts that the player's outcomes should be proportional to this "advantage." This "advantage" or weight is determined by the equation

$$P(C_j) = \frac{1/(n_j - 1)}{\Sigma 1/(n_j - 1)},$$

where $P(C_j)$ = the probability of coalition j, n_j = the number of members of coalition j and the summation is over all minimum winning coalitions. Thus, the AB coalition is predicted to form 40% of the time, and each of the three-player coalitions is predicted to form 20% of the time. The probability of inclusion for a particular player depends on the probabilities of the coalitions in which he or she is a member: Player i's probability of inclusion is equal to the sum of the probabilities of each of the coalitions he or she is a member of, $[\Sigma\, P(C_j),\ i \in C_j]$. In the 30(21–10–7–5–4) game, Player A will be included in all the winning coalitions ($P_A = 1.0$); the other players will each be included 40% of the time ($P_B = P_C = P_D = P_E = .40$). Player i's predicted payoff is proportional to his or her probability of inclusion:

$$R_{ij} = \frac{P_i}{\Sigma P_k};\ i, k \in C_j,$$

where R_{ij} = Player i's payoff (reward) in coalition j, P_i = Player i's probability of being included in a minimum winning coalition, and the summation is over all members of C_j. Payoffs in the AB coalition, then, should be 72–28; in the three-player coalitions, payoffs should be 55–22–22.

Although the original presentation of the weighted probability model (Komorita, 1974) made no predictions about the players' overall payoffs in a game (termed "success in bargaining" by Komorita and Moore, 1976), payoff predictions can be derived without additional assumptions. For any player i, the proportion of the total payoffs should equal the sum of the products of the player's predicted payoff in each coalition and the probability of that coalition. In the 30(21–10–7–5–4) game, Player A is included in every coalition and is predicted to receive a payoff of 72 on 40% of the trials and a payoff of 55 on 60% of the trials. Player A's overall mean payoff, then, should be 61.8. Player B, who should receive a payoff of 28 on 40% of the trials, should receive an overall mean payoff of 11.2. Similarly, for Players C, D, and E, the predicted mean payoffs are 8.8 each.

The Roth–Shapley Model

Unlike the weighted probability model, the Roth–Shapley model (Roth, 1977a, b; Shapley, 1953) does not predict the probabilities that different coalitions will form or the payoffs that members of the winning coalitions will receive. Rather, it specifies the proportion of the total payoff a player can expect from the play of a game.

The Roth–Shapley model is purely prescriptive: Its derivation depends only on a set of underlying assumptions concerning the format of the game. In games with constant payoffs for the winning coalition, this expectation is determined by dividing the number of times a player's resources are "pivotal" (in the sense that a losing coalition is converted to a winning coalition by the addition of this player) by the total number of permutations of the players. For instance, consider one permutation, DCEBA, in the 30(21–10–7–5–4) game. Because Player A holds veto power, he or she is the pivotal player in this permutation: The DCEB "coalition" can obtain no payoff without Player A. Indeed, in every permutation that places A third, fourth, or fifth, Player A is pivotal. Player A is also pivotal when Player B is first and A is second.

Player A is pivotal, therefore, in 75 of the 120 permutations that are possible. (In any five-person game, 51 permutations exist). Because Player B can form a winning two-player coalition with A, and the other players cannot, B will be pivotal more often than Players C, D, and E. In this game, B is pivotal 18 times, and C, D, and E are each pivotal 8 times. Dividing by the total number of permutations (120) yields expected proportions of the payoffs of (.65, .15, .07, .07, and .07) for Players A, B, C, D, and E, respectively.

The Core

As with most game-theoretic solution concepts (Murnighan, 1978a), the core (when it exists) identifies a stable payoff for each potential coalition, without predicting the relative frequencies of the different coalitions. The core is based on the concept of domination. One outcome dominates another if the members of a "new" coalition receive greater payoffs than they did before, *and* they have the power to enforce the new outcome. For example, in the 30(21–10–7–5–4) game, a coalition between A and B may form, giving A 80 and B 20. This outcome is dominated by an ADE coalition with a payoff of 90–5–5. In the ADE coalition, Players A, D, and E receive payoffs that are better than the payoffs they received in the AB coalition, and the ADE coalition can obtain the 100-point payoff. But just as the ADE (90–5–5) outcome dominates AB (80–20), every outcome can be dominated by one where Player A receives more and more points by forming a smaller coalition or one with previously excluded players. The only outcome that is *undominated* and therefore in the core of this game gives Player A the entire payoff. Although Players B, C, D, and E may not be disposed to accept this payoff, it remains the only undominated outcome and is the only outcome in the core. Like the Roth–Shapley model, the core is a purely prescriptive model; behavioral assumptions (e.g., about the players' willingness to obtain particular outcomes) are not incorporated into the model. Thus, this extreme prediction might not be expected to occur in an actual game. Nevertheless, the core implies that Player A's payoffs should increase as play in the 30(21–10–7–5–4) game continues. Indeed, whenever a game gives one player veto power, the core is the same, with the veto player receiving the entire payoff.

The core is included in, and for veto games subsumes, other game-theoretic models. In particular, the various forms of the bargaining set (Aumann & Maschler, 1964; Murnighan, 1978a) are all identical with the core for this game, and their predictions are also tested with, although not differentiated from, the core. Other game-theoretic literature (Aumann, 1964; Debreu & Scarf, 1963) also suggests that the core may result from very competitive play. Thus, support for the core would also suggest that the games used in this study were played very competitively.

Table 1 lists the predictions of each of the models for each of the games. Clearly the core makes more extreme predictions than either of the other two models. Differentiations between the weighted probability and the Roth–Shapley models are more difficult, as they have been in previous studies (Murnighan, 1978b; Murnighan & Roth, 1978). Only in the 28(17–8–7–6–5) game are the predictions very different, and then only for Player A. Thus, the data from the 28(17–8–7–6–5) game provide the best test of these two models. An additional test of the weighted probability model's predictions for the frequencies of each coalition can also be conducted. The model predicts equal frequencies for the minimum winning coalitions in the 20(17–6–5–4–3) and 28(17–6–5–4–3) games. For the 38(27–13–12–6–5) and the 30(21–10–7–5–4) games, the two-person coalitions should form twice as often as the three-person coalitions.

For the games in the Michener et al. (1976) study, the core prediction is the same as for this study; the weighted probability model predicted payoffs of 60–40 in AB coalitions, which should have formed twice as often as ACD coalitions (with 60–20–20 payoffs); and the Roth–Shapley value for the games is (58, 25, 8, 8), for overall payoffs. The data in that study show that Player A averaged well over 60 points in each of the games. For the Michener et al. (1976) study, then, both the weighted probability and

Roth–Shapley models underestimated the veto players' outcomes. Because each group played each of the games only once, it is impossible to determine whether the veto players' payoffs increased over trials. Nevertheless, their outcomes were a considerable distance from the core.

The present study affords a finer test of the models and also assesses the effects of "default" conditions, a manipulation of time pressures and aspirations, that are not incorporated into any of the models.

Time Pressure and Aspirations

Research on two-person bargaining has often manipulated the time bargainers are given to reach an agreement (e.g., Yukl, 1974). When both parties lose all or part of a payoff if they do not agree by a certain time, agreements tend to be more likely and the players' aspirations and demands tend to drop (Rubin & Brown, 1975). Time pressure has not, however, been systematically studied in coalition situations. In the present study, if no coalition formed after three attempts, one of three "default" conditions resulted: (a) All five players received a payoff of zero; (b) the veto player received 60 points, whereas each of the others received 10; or (c) bargaining continued until an agreement was reached (i.e., there were no defaults). These conditions might be expected to affect the aspirations of the veto and nonveto players differentially. For the veto player, either of the default conditions should lead to reduced aspirations, particularly as the third attempt to form a coalition approaches. In addition, the 60–10 default condition might be expected to lead to higher aspirations for the veto players than the zero default condition would (cf. Rubin & Brown, 1975). On the other hand, should the veto players' payoffs approach the core, as they did in at least one prior study (Murnighan & Roth, 1978), players may not perceive the two default conditions differently: Both may be regarded as serious setbacks.

For the nonveto players, the zero default condition might reduce each individual's own aspirations, compared to the no default condition. But there is always the possibility that "hurting" the veto player has positive value. Indeed, in previous research where the strongest of the players always received the letter "A" (e.g., Murnighan, 1978b), considerable anti-A feelings surfaced quickly. In addition, invoking the zero default may make Player A so cautious as to increase the nonveto players' payoffs in subsequent coalitions (cf. Murnighan & Roth, 1978). In the 60–10 condition, on the other hand, the nonveto players' aspirations should clearly increase. Only a small minority of the theoretical predictions (see Table 1) indicate that each of the nonveto players will be receiving 10 points on the average. Defaults, therefore, are advantageous to the nonveto players in this condition and should result in "tougher" bargaining (Bartos, 1970) even when defaults do not occur.

Considering the interactions of the default conditions with other aspects of the games, however, reduces the clarity of their potential effects. For instance, in the 60–10 default condition, the mixed-motive nature of coalition games removes restrictions on the potential payoffs that might result. Although pushing for a default as often as possible and refusing to take a payoff that is less than 10 points seems like a desirable strategy, the possibility of exclusion from the winning coalition, with loss of any payoff for that trial, may limit such a strategy's usefulness. Indeed, players who are willing to accept smaller payoffs typically are included more frequently in the winning coalition and also, at least in one study, accumulated larger overall payoffs (Murnighan & Roth, 1977). Thus the nonveto players are faced with a dilemma: Although pushing for a default payoff in either default condition may result in greater joint or long-term gain, a willingness to take a smaller payoff may potentially increase individual, short-term gain (cf. Thibaut & Kelley, 1959). Indeed, using strict definitions for rationality (Simon, 1976), individual nonveto players who reject payoffs that are greater than the default payoff on the third attempt are "irrational," at least in the short run. Add to this the possibility that giving deference to the powerful player may result in repeated inclusion in winning coalitions,

and it is clear that the nonveto players may be torn in several directions.

Although several pressures are inherent in these coalition situations, the effect of aspirations is predicted to lead to higher payoffs for the veto player in the no default condition compared to the zero and 60–10 conditions. A priori predictions contrasting the 60–10 and zero default conditions, however, are difficult to make.

Method

Subjects

Subjects were 120 master's-level students enrolled in a behavioral science course in a commerce department. For the most part, these students had little or no previous background in behavioral science. To complete the project requirements in the course, students had a choice between writing a library research paper or participating in the bargaining exercises and completing a paper analyzing their own strategies in each of the games. The performance in either option accounted for 15% of the grade in the course. Students who participated in the bargaining exercises (presented as "exercises in strategy selection") were informed that their performance in the games would be compared to the performance of other students in the same positions (i.e., with the same vote total) as themselves. Students could obtain an "A" grade for the project in any of three ways, by: (a) scoring better than the average total points for players *in the same position as themselves*, (b) scoring above the mean for similarly positioned players in the other groups in three of the four games, (c) doing an excellent job of analyzing their strategies in their paper. All students, regardless of their game performance, were required to complete the paper. Only with a relatively poor paper and below average performance in the games would a student earn a "B" for the project.[2]

Graduate students were used in this study in an attempt to parallel "real world" coalition bargainers more closely. Although none of the theories tested here speak to the expertise of the populations they address, it seems that most individuals involved in coalition bargaining, such as the examples mentioned earlier (Middle Eastern oil producers, corporation executives, and members of the United Nations Security Council), are both more intelligent and more experienced in bargaining situations than the general population. Including graduate students who have some stake in the outcomes of the bargaining and who are given repeated experience with coalition bargaining should more closely mirror such a population (cf. Murnighan, Note 1).

There were 24 5-person groups in all: 6 composed of 5 males; 7 with 1 female and 4 males; 8 with 2 females and 3 males; 2 with 3 females and 2 males; and 1 with 4 females and 1 male. Most of the 33 female participants were commerce majors.

Design and Analysis

A number of factors were manipulated in this study. Each group played each of the four games for a total of 12 trials in one of the three default conditions. Thus, games and trials were within-group variables, and default conditions was a between-group factor. Each game was played by five players, one in each of the A, B, C, D, and E positions; players were assigned different positions in the different games. Thus, player positions was a within-group variable. Finally, the games were played in one of eight different orders. Two Latin square designs were used to assign groups to the eight game–order combinations. Thus, each game was played an equal number of times in each order. The variable called "order," then, merely indicates whether a game was played 1st, 2nd, 3rd, or 4th for each group. The final design (see Table 2), then, included five crossed factors: games (4), default conditions (3), trials (12), player positions (5), and order (4), with two subjects in each unique condition. The between-group variables, again, were default conditions and order.

Because the players may have discussed the games with each other, their behavior in the games may not have been strictly independent, violating one of the assumptions of analysis of variance. To attempt to correct for this deficiency, the conservative test proposed by Box (1954), discussed by Winer (1962), was used in all analyses for the repeated factors. Although the value of the F ratios remains the same in each case, the degrees of freedom are considerably reduced. For instance, for the main effect of games on the veto player's payoffs, the normal degrees of freedom are 3 and 12; for the conservative test, the degrees of freedom are reduced to 1 and 4.

Procedure

The participants were given instructions about the coalition games in the third class of the semester, prior to the first session. Several examples of the use of the procedure (in games not used later) were discussed. Theories on bargaining were *not* included in this discussion and were only discussed after completion of the exercises. The players were told that there would be 12 trials in each game, and on each trial the winning coalition would divide a prize of 100 points among its members. They were instructed to do as well as they could (i.e., maximize their

[2] Participation by students from an instructor's own class can raise ethical issues concerning potential coercion. A copy of the safeguards taken by the authors to guard the rights of the participants in this study is available on request.

Table 2
The Assignment of the 24 Groups to the Condition–Order–Game Combinations

Condition and order	Game			
	20(17–6–5–4–3)	38(27–13–12–6–5)	30(21–10–7–5–4)	28(17–8–7–6–5)
No default				
1	4, 7	3, 8	2, 6	1, 5
2	3, 6	2, 7	1, 5	4, 8
3	2, 5	1, 6	4, 8	3, 7
4	1, 8	4, 5	3, 7	2, 6
Zero default				
1	12, 15	11, 16	10, 14	9, 13
2	11, 14	10, 15	9, 13	12, 16
3	10, 13	9, 14	12, 16	11, 15
4	9, 16	12, 13	11, 15	10, 14
60–10 default				
1	20, 23	19, 24	18, 22	17, 21
2	19, 22	18, 23	17, 21	20, 24
3	18, 21	17, 22	20, 24	19, 23
4	17, 24	20, 21	19, 23	18, 22

Note. Each of the groups included Players A–E; they played each game for 12 trials.

points) because their performance would (and did) determine part of their course grade.

Students were randomly assigned to groups, with the constraint that members be unacquainted. Each group met for their sessions at the same hour each week for four weeks. They were told which game they would be playing each week, but not which position they would hold throughout each game. Participants were told that they would not be in a "strong" position more than once. They were allowed to discuss the games with other members of their class, excluding members of their own group. In addition, the players were encouraged to formulate strategies for each position prior to each game.

Each group played each of the games for a total of 12 trials, where a trial was defined as the formation of a winning coalition. For each game, player positions were designated A, B, C, D, and E, with Player A having the most resources, Player B having the second most resources, and so forth. Assignment of players to positions was predetermined by randomly assigning members of each group to a particular "slot." The slot was unknown to the players and indicated what position each player would play in each of the four games. For instance, the first slot might mean that an individual would be assigned Player Position A in the 30(21–10–7–5–4) game, B in the 20(17–6–5–4–3) game, and so forth. The assignments within each slot were determined randomly, with the constraint that no player would be assigned the A position more than once and that the player who was not assigned to the A position in any game was given the B position in the 30(21–10–7–5–4) game. These constraints were rough attempts to establish equity among the assignments.

During the games, the players were seated around a set of opaque partitions that shielded them from view of each other and the experimenter. At each group's first session, the experimenter read specific instructions about the procedures for the games. The players made offers on each trial by means of written offer slips, which required indicating to whom one wished to send offers and also a proposal regarding the division of rewards for the prospective coalition members. For example, if Player X wished to form an XY coalition, he or she addressed an offer to Player Y and specified a division of the rewards (e.g., 60 for X and 40 for Y) on the offer slip. A player was required to send an offer slip to each player included in the proposed coalition. Thus, if a player proposed a three-person coalition, two identical offer slips were sent, one to each of the proposed coalition partners. Players were also told that they could not send an offer to one person to form one coalition and a second different offer to another person to form another coalition. This procedure, originally used by Komorita and Meek (Note 2), allowed two-, three-, and four-person coalitions to form in a single step. Thus, although large coalitions may be more difficult to form, the only difficulty inherent in this procedure is the need to fill out additional offer slips. After the players had completed the offers, the experimenter collected, examined, and distributed them to the proper persons.

After receiving an offer, each person could accept or reject it by marking "Accept" or "Reject" at the bottom of each offer slip. A person receiving more than one offer could accept at most one, unless the offers proposed the identical payoff division for the same coalition. Hence each person could only accept offers to form a single coalition on each trial. Furthermore, in determining a winning coalition, any

player's proposal, if accepted, had priority over any offer he or she might accept, thus committing the player to his or her own offer. After the offers had been accepted or rejected, the experimenter collected the offer slips and announced the winning coalition, if one had formed, and the payoff division. A coalition was declared winning if all the proposed coalition partners accepted the offer. If no coalition formed because at least one person rejected each of the proposed coalitions, the procedure was repeated. This procedure allowed for acceptance within the group of two proposals on the same trial. For instance, if A sent an offer to C, D sent an offer to A, and both offers were accepted, AC would be declared the winning coalition because A was committed to his or her offer (invalidating his or her acceptance). While the offer D sent to A did not result in a coalition, it indicated the exact nature (i.e., how much D was willing to offer) of D's interest. When two coalitions were accepted in this manner, such that each was invalidated by the other (e.g., ACD and ACE), the players were informed of the situation and the trial was rerun.

A practice trial was conducted before the start of the first session. Immediately after the practice trial, the players were assigned to their positions for that game. Lists of the resources (i.e., votes) for each position and the winning coalitions were also provided. No verbal communication was permitted thereafter; hence, the players could not identify each others' positions.

The instructions were summarized for the players at the start of their second, third, and fourth sessions. Practice trials were not run, but assignment to one of the five positions and information about the resources for each of the positions and the winning coalitions were distributed *after* the players were seated behind the partitions. Thus, for each game, the players were not informed of the identity of the players in the other positions.

Lengthy discussions of power, coalition, and bargaining theories were conducted during several classes at the end of the semester. The central focus in each of these discussions was the students' behaviors during the exercises and their analyses of strategies in their papers. Individuals were not identified in these discussions, and all other questions were answered.

Results

Sex Effects

Vinacke (1959) and Komorita and Moore (1976) have reported that males tend to be, in Vinacke's terms, "exploitative" and that females tend to be "accommodative" in coalition situations. There appeared to be no effects due to sex in this study: Males tended to obtain overall payoffs as veto players only marginally higher than females did (89.8 vs. 87.2); similarly, females obtained only marginally higher payoffs as nonveto players (2.6 vs. 2.3). However, the random assignment of players to slots resulted in a disproportionate number of male veto players in the 20(17–6–5–4–3) game. Thus it is difficult to make firm conclusions.[3]

Coalition Frequencies

Because each game resulted in a different set of minimum winning coalitions, the frequencies of the different coalition types were analyzed in four analyses of variance, one for each game. Thus, four Default (3) × Order (4) × Trial Block (3 blocks of 4 trials each) × Coalition Type (which differed over games, see Table 1) analyses of variance were run, with the frequencies of each coalition type converted to arcsin values[4] as the dependent variable in each case. Trials where nonminimum winning coalitions formed (not predicted by any of the models, and occurring only 2% of the time) or where defaults resulted were not included in these analyses. The data are shown in Table 3.

In the 28(17–8–7–6–5) game, significant effects were found for default conditions, $F(2, 12) = 3.92$, $p < .05$, and the default by coalition type interaction, $F(10, 60) = 2.44$, $p < .05$. The default main effect merely reflects the fact that due to a total of 15 defaults in this game, there were more coalitions forming in the no default condition than in the two default conditions. The Default × Coalition Type interaction appears to be primarily a result of an unusually high frequency of ABD coalitions in the no default condition and relatively equal frequencies for the other coalitions in each default condition.

In the 30(21–10–7–5–4) game, the only significant effect was for coalition type, $F(3,$

[3] Indeed, because there were no female veto players in the no default 20(17–6–5–4–3) condition, reliable statistical analyses were not possible.

[4] The transformation used was

$$x' = 2 \arcsin \sqrt{x},$$

where x is expressed as a proportion of the maximum possible frequency for any coalition within a trial block. Also, for $x = 0$, $1/(4n)$ (where $n = 4$) was used; for $x = 1$, $1 - 1/(4n)$ was used (Bartlett, 1947).

Table 3
Coalition Frequencies and the Predictions of the Weighted Probability Model (in Parentheses)

Game	Coalition										
	AB	AC	AD	AE	ABC	ABD	ABE	ACD	ACE	ADE	Default
20(17–6–5–4–3)	80 (72)	62 (72)	50 (72)	80 (72)	1	0	0	0	1	2	0
38(27–13–12–6–5)	88 (112)	111 (112)	—	—	1	0	0	0	1	81 (56)	6
30(21–10–7–5–4)	134 (112)	—	—	—	1	1	0	40 (56)	45 (56)	59 (56)	5
28(17–8–7–6–5)	—	—	—	—	41 (48)	48 (48)	45 (48)	29 (48)	51 (48)	57 (48)	15

Note. Totals do not always add to 288 because of the exclusion of infrequent coalitions such as ABDE, ACDE, etc. Coalitions that were not predicted to form have no parenthetical entry.

36) = 13.91, $p < .0001$. Post hoc tests indicated that the AB coalition ($n_{AB} = 134$) formed significantly more than either ACD, ACE, or ADE (ns = 40, 45, 59, respectively). In the 38(27–13–12–6–5) and 20(17–6–5–4–3) games, no significant effects were found.

These data show some support for the weighted probability model's frequency predictions (see Table 3). In the 28(17–8–7–6–5) and the 20(17–6–5–4–3) games, only one effect was significant for coalition types (a Default × Coalition Type interaction), primarily resulting from a high frequency for one coalition type in one particular condition. No main effects were found for coalition types; overall, then, the weighted probability model's predictions in these two games were supported. In the 30(21–10–7–5–4) game, the AB coalition was significantly more frequent than the three-person coalitions, as predicted. However, it was considerably more frequent than even the model predicted. Finally, in the 38(27–13–12–6–5) game, there were no significant differences among the coalitions, although the model predicts that AB and AC will each form twice as frequently as ADE. Thus the model receives only marginal support, in the two games where equal likelihood predictions are made.

The Veto Players' Payoffs

The veto players' payoffs were analyzed in two Default (3) × Game (4) × Trial (12) × Order (4) analyses of variance, one including the default payoffs, the other excluding them. Because the results of the two analyses were almost identical, the data excluding the default payoffs will only be presented when the outcomes of the analyses differed. In addition, because the distributions of player A's payoffs were negatively skewed, both in the entire distribution and within almost every cell of the design, medians and means for significant effects are reported. Although the analysis of variance is robust with respect to skewed distributions, reporting the medians may be a better representation of the central tendency within each cell.[5]

Significant main effects were found for games, $F(1, 4) = 19.83$, $p < .05$, for trials, $F(1, 12) = 9.93$, $p < .01$, and for order, $F(1, 12) = 6.85$, $p < .05$, and were marginally significant for the default conditions, $F(2, 12) = 3.12$, $p < .10$. Post hoc tests using the Neuman–Keuls procedure indicated that the veto players received significantly more in the 20(17–6–5–4–3) game than in the 38(27–13–12–6–5) or 30(21–10–7–5–4) games and received the lowest payoffs in the 28(17–8–7–6–5) game (see Table 4). The veto players' payoffs consistently increased over trials. Player A received significantly less in the first game played ($M = 84.4$, $Mdn = 90$), and no differences, again using the Newman–Keuls technique, were noted among the other orders ($91.1 \leq M$s ≤ 92.5, $95 \leq Mdn$s ≤ 97). The marginal default effect suggests that Player A received the highest payoffs in the no default condition. This effect disappeared, however, when the default trials were removed, $F(2, 12) = 2.17$, *ns*.

[5] Tests of homogeneity, using Huynh and Feldt's (1970) chi-square test, were also run for each of the significant effects. (The small sample size precluded an overall test.) None of the chi-squares reached significance at the .05 alpha level.

Nonveto Players' Payoffs

The analysis of the nonveto players' payoffs was similar to those for Player A but included an additional factor, the players' positions (i.e., B, C, D, or E). The effects that do not include the players factor reproduce the results for the veto players' payoffs and are not reported. The significant effects that did include the players factor were the players main effect, $F(1, 12) = 15.10$, $p < .01$, and the Games × Players interaction, $F(3, 9) = 3.98$, $p < .05$. Table 5 displays the means for the Games × Player interaction and the associated main effects. Post hoc tests indicate that Player B received significantly higher payoffs than the other players in the 30(21–10–7–5–4) game did and that Players B and C received significantly higher payoffs than Players D and E in the 38(27–13–12–6–5) game. In both cases, then, nonveto players who held positions that allowed for the formation of a two-person coalition with Player A received significantly higher payoffs than nonveto players did in the same game who were required to form three-person agreements.

In addition, combining the mean payoffs for players who were required to form three-person coalitions compares very favorably to the mean payoffs for players who could form two-person coalitions. For instance, in the 30(21–10–7–5–4) game, combinations of Players C and D's payoffs, C and E's payoffs, or D and E's payoffs range from 3.88 to 4.10; Player B's mean payoffs of 4.00 are almost identical. Thus, it appears that, across the coalition type, the payoffs of the veto player's partnership sets were fairly stable within a game. This result is predicted by several game theoretic models (e.g., Aumann & Maschler's, 1964, bargaining set).

One way to explore the determinants of the veto players' payoffs is to investigate the correlations between their payoffs and the offers they received, along with their own demands. It has been suggested that players who are

Table 5
Mean Payoffs for the Nonveto Players in Each Game, Including Default Payoffs

Game	Player				*M*
	B	C	D	E

Note. Means with common subscripts within a main effect or the interaction are *not* significantly different from one another at the .05 level using the Newman–Keuls procedure.

given veto power can obtain almost any payoff they desire, at least when there are no default conditions (Murnighan & Roth, 1978). In this study, Player A's demands (his or her offers to self) were more highly correlated (significantly) with A's payoffs than were either the mean of the nonveto players' offers or the highest of the nonveto players' offers. Player A's payoffs and demands showed a correlation of .94 ($n = 1126$) when default payoffs were excluded and correlations ranging from .88 to .98 in the four games. The highest of the nonveto players' offers revealed an overall correlation with A's payoffs of .76, with correlations ranging from .66 to .83 in each of the games. Needless to say, each of these correlations is significant. More important, in each game the correlations between A's payoffs and A's demands were significantly higher (using two-tailed t tests, Edwards, 1967, pp. 250–251) than the corresponding correlations between A's payoffs and the nonveto players' offers. It appears, then, that veto players controlled their payoffs more than the nonveto players, replicating previous findings (Murnighan & Roth, 1978), even when defaults were possible.

Defaults

The frequency of defaults in the game/default conditions is shown in Table 6. Given the total of only 26 defaults, reliable statistical analyses cannot be used on these data. In addition to the data in the table, which suggest that the 60–10 default condition and the 28(17–8–7–6–5) games led to more frequent defaults, defaults were more frequent early in each session, in the first set of four trials ($n = 15$), rather than later, in the second (6) or third set (5).

The frequency of trials that reached at least three attempts is also shown in Table 6. The data suggest that reaching the third attempt was most likely to lead to a default in the 28(17–8–7–6–5) and 38(27–13–12–6–5) games in the 60–10 default condition.

The uneven distribution of trials that reached three attempts necessitated a least squares analysis of variance of the offers to the veto player over the three attempt trials. Using default conditions (3), games (4), players (5), and attempts (first, second, and third) as independent variables, the results yielded a suggestive interaction between default conditions and attempts, $F(1, 50) = 3.84$, $p < .07$. The means in the interaction suggest relatively stable, slightly increasing offers to A over the three attempts in the no default and zero default condition and decreasing offers to A in the 60–10 condition. Even in this condition, however, the mean offers to A dropped only slightly, from 83.3 to 80.6.

Discussion

The results clearly do not support the weighted probability and Roth–Shapley models. Just as they did in the Michener et al. (1976) study, the veto players' payoffs far exceeded the predictions of either model. Although the weighted probability model received some support from the data on coalition frequencies, it consistently underestimated the veto players' payoffs. The Roth–Shapley model is similarly inadequate, even though its predictions are somewhat closer to

Table 6
Frequency of Defaults in Each Game/Default Condition

Default	Game 28	30	38	20	Total
None	– (21)	– (10)	– (2)	– (4)	– (37)
Zero	7 (13)	0 (13)	2 (6)	0 (2)	9 (34)
60–10	8 (15)	5 (14)	4 (8)	0 (4)	17 (41)
Total	15 (49)	5 (37)	6 (16)	0 (10)	26 (112)

Note. The frequency of trials that reached three attempts is shown in parentheses.

the data. The models received some very marginal support from the players' payoffs for the significant differences that were found for nonveto players who could form two-player coalitions in the 38(27–13–12–6–5) and the 30(21–10–7–5–4) games: Even though these players' payoffs were smaller than predicted, they were significantly larger than those of players in the same games who were required to form at least three-person coalitions with Player A, as predicted. Also, in rank ordering the players' payoffs, both the models did fairly well (rank correlation coefficients between observed and predicted payoffs of .93), suggesting a correct depiction of the games' structures, if not the specific outcomes.

The core, on the other hand, was clearly not reached. However, the payoffs of the veto players consistently moved toward the core in each of the four games studied. The core is also not supported by the significant difference found among the four games. In addition, the payoffs for the veto players in the 28(17–8–7–6–5) game were considerably below those in the core. Even in this game, however, the payoffs consistently increased over trials. In addition, the consistently strong correlations, across games and the other conditions, between the veto players' demands and payoffs strongly suggests that they had control of their payoffs. Just as Murnighan and Roth (1978) found that when the veto players demanded 99% or more of the payoff, over 90% of the time they were receiving it, so too the present data suggest near-complete control for the veto player. Whether veto players could push their payoffs closer to the entire payoff if they were tougher in their demands remains to be tested in future research. This study, along with other recent research (e.g., Fiorina & Plott, 1978; Murnighan & Roth, 1977, 1978), shows promise for the predictive capabilities of the core.

The findings, then, clearly do not offer strong support for the weighted probability model, the Roth–Shapley value, or the core. Each received marginal support, however: the core by the increasing payoffs received by the veto players and the other models by their ordering of the magnitudes of the players' payoffs across games. The effects for games and for trials stand out and suggest that a combination of the properties of the two kinds of models may be necessary to predict the outcomes of coalition bargaining games that include a veto player. Komorita and Chertkoff's (1973) bargaining theory, although not testable in veto games, suggest that payoffs will change over trials, increasing for the most powerful player, as they have here. The difficulty in directly adapting such an insight is in determining where a veto player's payoffs will begin and where they will end. In the present study, the final median payoffs of the veto player were adequately, but not perfectly, represented by the core. The starting points were quite close to values midway between the core and either the weighted probability or Roth–Shapley models (i.e., 90, 85, 81–82, and 75–80 in the 20, 38, 30, and 20 games, respectively). A model that incorporates trials as a factor, with a veto player's payoffs increasing from such a core-weighted probability – Roth-Shapley midpoint on the early trials to the core on later trials, dependent on the game being played, would explain this study's data fairly well. Difficulties arise, however, in conceptually justifying such predictions in a logical way. In addition, the different conditions that surround the bargaining situation, including, for example, the physical separation of individuals, as was the case in this study, may also determine the magnitude of the payoffs obtained by the bargainers. Given the fact that few studies have been conducted on the dynamics of games that include veto players, further research, even of an exploratory nature, might contribute sufficient information for the construction of theoretical propositions that are viable both conceptually and empirically. Given the current lack of clear-cut results, it appears that not enough is understood about veto games to present such a theory.

The effects for the other variables studied here, order and the default conditions, were somewhat unexpected. The players were given considerable preparation before the game; nevertheless, most expressed the belief that the first session was needed to establish the firsthand understanding necessary to bargain effectively in the games. Indeed, players in

the A position tended to increase their payoffs, especially in the 28(17–8–7–6–5) game, after their first game. These results suggest that experience may be a key factor in coalition research, if not in "real world" situations. Whereas most research on coalitions asks participants to play in only a single session, this study highlights the effects of experience, suggesting that stability is only achieved after a rather involved first experience.

The lack of effects found for the default conditions was particularly surprising. It would seem, at least, that the default conditions should have constrained Player A's ability to obtain such high payoffs. The fact that one player has veto power in each of the games appears to have overwhelmed any effects of this manipulation. Combined with the results from Murnighan and Roth (1978), the conclusion that veto players can and will ruthlessly pursue their own rewards is difficult to refute. Indeed, these results support the widely held assumption that strict controls are necessary to restrain monopolistic organizations.

There are occasions, however, when more socially beneficial behaviors result. In this regard, it is important to describe one "exceptional" group that played the 28(17–8–7–6–5) game first, in the no default condition. At the start of the game, the veto player made a proposal of 60–20–20 (60 points for himself, and 20 for two of the other players). After a few rejections, this agreement was finally achieved. Even though Player A continuously received offers exceeding 60 points, he *enforced* 60–20–20 payoffs on every trial, rotating among the nonveto players to insure equal outcomes for each of them. By the end of the session, all of the players were exchanging 60–20–20 offers. This group's first session was interesting—their second was remarkable! The new veto player, now playing the 38(27–13–12–6–5) game, demanded 98 of the 100 points on his first offer. He received four offers of 60–20–20! Inflexibility of both A and the nonveto players resulted in 32 unsuccessful attempts prior to the formation of the first coalition. And the payoff finally agreed upon in that coalition was 60–20–20. It appears that a norm had developed: Payoffs of 60–20–20 were defined as appropriate; others were not. Although this norm gradually eroded (due mainly to the impatience of players who were excluded from the winning coalition), the veto players in this group received payoffs that were considerably below the mean over all veto players, in each of the four games. The nonveto players, on the other hand, were above the mean for their position for each of the games. According to the grading system announced prior to play, scoring above the mean for all players in the same position in three out of four games (or above the overall mean) would insure an "A" for the project. Thus, all five players in this group received an "A"!

Clearly this was an unusual group. However, one explanation for the group's success is that the first veto player's strategy provided this individual with a chance to obtain a high grade for himself *and* contribute to a high grade for the other players in the group. Unlike prisoners' dilemma games, then, where individual and group gains are generally in conflict, coalition games like these offer players at least one strategy that can be implemented to maximize both individual and group outcomes.

Conclusion

In summary, this study investigated four coalition games that included a veto player. The games varied the number of two-person coalitions that the veto player could form to obtain a fixed payoff in three default conditions. The games had a significant effect on the veto players' payoffs, with payoffs diminishing as fewer two-person coalitions were possible. The other noteworthy effects included support for the core, particularly because of the consistently increasing payoffs for the veto player. The default conditions had little impact on the results. Indeed, the lack of significant effects for this variable suggests that players with veto power can control the game they are playing almost at will. These results further illustrate the need for controls of some kind for monopolistic organizations. Future research might also investigate the effects noted in the one "exceptional" group: When

joint gains can be tied to higher individual gains (or at least potentially higher individual gains), then (and possibly only then) cooperative, group-oriented behaviors may emerge (cf. Argyris, 1957). Indeed, the incidence of cooperative behavior in highly competitive situations such as those in this study has rarely been investigated (an exception is Dawes, McTavish, & Shaklee, 1977) and would help to move research on coalitions into the determination of structural mechanisms to increase cooperation.

Weather, Mood, and Helping Behavior: Quasi Experiments With the Sunshine Samaritan

Michael R. Cunningham
Elmhurst College

To establish the relationship of weather variables with helping behavior, two quasi-experimental field studies were conducted. In the first study, executed in the spring and summer and subsequently replicated in the winter, the amount of sunshine reaching the earth was found to be a strong predictor of a participant's willingness to assist an interviewer. Smaller relationships were also found between helping and temperature, humidity, wind velocity, and lunar phase. A second study was conducted indoors to control for comfort factors, and sunshine, lunar phase, and participant's age and sex were found to predict the generosity of the tip left for a restaurant waitress. Sunshine and temperature temperature were also significantly related to self-reports of mood.

So many things I would have done, but clouds got in my way. . . . (Joni Mitchell, "Both Sides Now")

One of the most pervasive background environmental variables in human life, a factor that shapes agricultural economies, makes or breaks recreational plans, and serves as a perennial topic for superficial conversation, is the weather. Yet although the weather appears to affect both emotion and social behavior (Campbell & Beets, 1977; for reviews, see Huntington, 1945; Larson, 1965; Moos, 1976; Tromp, 1974; Winslow & Herrington, 1949), the specific weather variables most closely associated with behavior changes remain obscure.

A brief scan of some of the research literature will illustrate the wide variety of meteorological indices purportedly linked to various human behaviors.

Dexter (1904), for example, found very low barometric pressure, excessive humidity, and abnormal winds to be related to poor student deportment and increased teacher use of corporal punishment. Deteriorating or stormy weather has also been related to reduced task performance by workers (Muecher & Ungeheuer, 1961). Weather has also been implicated in psychological disturbances; Mills (1934) and Digon and Bock (1966) found a relationship between low barometric pressure, which usually characterizes stormy days, and suicide, whereas Lester (1970) obtained a relationship between the amount of snow during the winter months and the frequency of suicide.

The sky conditions may also affect mood or psychological well-being. Winslow and Herrington (1936) found a correlation of .78 between the amount of sunshine apparent on a given day and judgments of atmospheric "pleasantness" (associations were also found with increased barometric pressure and decreased humidity). Finally, Persinger (1975) observed that low moods in his 10 subjects were associated with fewer hours of sunshine and high humidity.

Although the foregoing studies suggested that weather may influence emotion and be-

Thanks to Thomas Brothen, Charles Carver, Carolyn Cunningham, William Graziano, Alice Isen, Michael Louguee, Paul Rosenblatt, Catherine Thayer, Sandra Titus, and Hans Wendt for their insightful comments on an earlier draft of this manuscript. Grateful appreciation also to Paul Cronstrom, Mike Fleming, Ruth Nachman, Linda Rudin, and Cindy Weber for their help as experimenters, and to the staff of the Minneapolis–St. Paul station of the National Weather Service and the manager and waitresses of Henrici's Restaurant for their invaluable assistance.

Requests for reprints should be sent to the author, Department of Psychology, Elmhurst College, Elmhurst, Illinois 60126.

havior, straightforward conclusions are difficult. In no study have all of the implicated weather variables been considered simultaneously to determine the relative strength of their relationships with behavior. In addition, a number of the studies suffered from the methodological weakness of using indices based on the average level of a given weather variable, and the frequency of a certain behavior within relatively wide time blocks, such as a day, week, or month, to establish a relationship (e.g., Banziger & Owens, 1978). But since a day or week in which temperatures varied from 30 °F to 70 °F (−1 °C to 21 °C) produces a different experience from a stable 50 °F (9 °C) day, such summary statistics may be highly misleading. Further, if weather and behavior are not sampled concurrently, it is difficult to eliminate the argument that purported weather effects are due to some third variable or by-product of the weather (e.g., mobility restriction).

The use of experimentally controlled environments would eliminate these objections. Griffitt and Veitch (1971) found that under conditions of manipulated high temperature, participants' evaluation of both other people and the experimental environment was significantly more negative than under conditions of comfortable temperature. Corresponding changes in the participant self-ratings of affect suggest that the temperature effects probably were mediated by alterations in the individual's mood. Subsequent work has indicated that there may be an upper limit to the temperature–aggression relationship; too much heat may actually inhibit aggression (Baron & Bell, 1976).

Yet although temperature can be easily manipulated, controlling humidity, barometric pressure, wind velocity, and amount of sunshine in a factorial design seems unfeasible. A compromise would be to adopt a quasi-experimental design (Campbell & Stanley, 1963) in which uncontrolled variations in the weather are systematically observed and related to changes in a carefully measured dependent variable using randomly selected subjects.

Helping or altruism is a social behavior that has been found to vary as a function of the mood or emotional state of the subject (Cunningham, Steinberg, & Grev, in press). If the weather affects individuals' emotional state or sense of well-being, then it might be expected to affect helping, and two studies tentatively suggested such a relationship. Lockard, McDonald, Clifford, and Martinez (1976) reported that panhandlers were more successful in spring than in autumn, and Cialdini, Vincent, Lewis, Catalan, Wheeler, and Darby (1975) footnoted a similar observation. Neither study, however, connected a specific weather variable to an increase in helping.

The present series of studies was designed to assess the impact of a variety of weather, climatic, and air quality indicators on helping, using two different indices. The first study, concerned with helping an interviewer, was initially conducted outdoors during the late spring and summer and was subsequently replicated during the winter. The second study involved restaurant tipping, and data were collected indoors during the early spring.

Predictions for the effects of weather on both forms of helping were drawn from the results of the earlier research. Since behavior seemed to be adversely affected by low barometric pressure and high humidity, negative correlations were predicted for those variables with interpersonal helping. Although previous research has found only that mood was adversely affected by high temperature, it is reasonable to imagine that mood may be depressed by the cold as well. An inverted U-shaped relationship was thus predicted for temperature and helping, with the most helping expected at moderate temperatures. Finally, since mood seemed to be affected by sunlight, a positive correlation was predicted between helping and the amount of sunshine reaching the earth due to the absence of cloud cover.

Experiment 1

Method

Participants. Data were gathered outdoors from 540 participants at two off-campus locations in the city of Minneapolis and two locations on the main campus of the University of Minnesota. Every 3rd individual over the apparent age of 16 passing the experimenter was approached, and the estimated age

and sex of the subject were recorded. Fifteen participants were approached each day during the afternoon on 36 weekdays randomly selected during the spring and summer of 1974 and the winter and early spring of 1974–1975. An average of 4 people each day refused to stop for the study and were not included in the primary analyses. Temperatures ranged from −18° C to 38° C. Data were not collected during any periods of precipitation.

Procedure. One male and one female were employed as experimenters each season. One female was used in winter and another in summer. One experimenter was blind to the purposes of the experiment each season. The measure of helpfulness was obtained by approaching passersby with the statement:

> Hi. I'm from the sociology department of the University of Minnesota and we're conducting a survey of social opinions. Although the survey is 80 questions long, you don't have to answer all the questions. How many questions would you be willing to answer for me?

The number of questions the participant was willing to answer was employed as an interval measure of helping. Participants were then debriefed following their response.

Weather readings taken at the beginning of the specific hour in which the participants were approached were employed as predictor variables. Separate estimates were obtained of the amount of sunlight reaching the earth, atmospheric temperature, barometric pressure, relative humidity, wind velocity, and lunar phase. To determine if changing weather had an effect, the increase or decrease in temperature and barometric pressure over the last hour and last 3 hours prior to the behavioral measurement was calculated. Three measures of air pollution were also included: carbon monoxide, sulfur dioxide levels, and Apex, a weighted composite of CO, SO_2, and particulate levels. Weather readings were obtained from the National Weather Service, Minneapolis–St. Paul Forecast Office, with the exceptions of sunshine level, which was obtained by incident light reading using a Gossen Luna-Pro light meter, and lunar phase, obtained from an almanac.

Results

Preliminary analysis revealed no association between the age and sex of the subjects or location and the weather variables. This independence, and the well-trafficked public places used for sampling, supported the assumption of random assignment of subject to weather conditions and the employment of each subject as an independent case. There was also no association between experimenters and helping.

A general regression equation was computed for the summer, the winter, and the combined data, using the 13 weather variables as predictors of helping. Each of the three regression equations—for the summer, $F(13, 256) = 7.41$, $p < .001$; winter, $F(13, 256) = 7.47$, $p < .001$; and combined sample, $F(13, 526) = 8.99$, $p < .001$—was highly significant and, analogous to a significant overall F test in analysis of variance (ANOVA), justified examination of the individual correlations. The Pearson correlations between the weather variables and helping are presented in Table 1.

The most significant variable in this study, across both summer and winter, was sunshine. People were likely to be more helpful when the sky was clear and a large amount of sunshine was striking the earth, compared to when the sky was cloudy and less sunlight reached ground level. The positive association of sunshine with helping can apparently not be attributed to temperature, since the correlation between the two variables was moderate, $r(538) = .29$, $p < .001$, and in the partial correlation analysis described below, both variables contributed independently to the prediction of helping.

Temperature was also a significant predictor of helping, although the nature of the relationship varied from summer to winter. Consistent with predictions, temperature was negatively associated with helping in the summer and positively related to helping in the winter. To determine if the relationship of temperature with helping was nonlinear, a curvilinear equation was constructed. Temperature scores were divided into seven equal intervals and were weighted to produce a curve with an apex centering about 19 °C (65 °F), consistent with the experimentally obtained optimal outdoor temperature for clothed active individuals (Yaglow & Miller, 1925). The correlation of the curvilinear equation with helping was positive, $r(538) = .30$, $p < .001$, and was significantly better than the linear relationship of temperature with helping, $z = 2.11$, $p < .02$.

Further, both sunshine and the curvilinear temperature index were employed in a general regression equation to predict helping. Both sunshine and curvilinear temperature were significant, $F(2, 537) = 55.82$ and 31.11, re-

Table 1
Correlations of Weather and Subject Variables With Amount of Help Offered an Interviewer

* $p < .05$. ** $p < .01$. *** $p < .005$.

spectively, $p < .001$, with sunshine accounting for 13% and curvilinear temperature accounting for 5% of the total variance in helping.

Another predicted significant association found in this study was a negative correlation between relative humidity and helping. People were more likely to be helpful when the humidity was low than when the humidity was high.

As a converse to temperature, wind velocity was positively correlated with helping in the summer but negatively correlated with helping in the winter. This is reasonable, since a cooling breeze provides a desirable relief from summer heat but is an undesirable contributor to wind chill in the winter months.

Unexpectedly, a small negative relationship was found between lunar phase and helping. In both summer and winter, people seemed to be less helpful when the moon was full than when the moon was less full. Further analyses reported below, however, raise questions concerning this relationship.

A number of other correlations of weather variables with helping appear in Table 1 for one season but not for the other. Each of these variables correlated more highly with another weather variable than they did with helping, and they must be regarded as unreliable until they are replicated.[1]

Partial correlation analyses were conducted to determine the relative independence and strength of the significant weather variables including sunshine, temperature, relative humidity, wind velocity, and lunar phase. The results of these analyses for the summer, winter, and combined sample are presented in Table 2.

The partial correlation analysis revealed that sunshine, temperature, relative humidity, and wind velocity were each significantly related to helping in the summer, in the same directions as in the zero-order correlations. A regression equation using these four predic-

[1] A number of derived statistics involving combinations of various weather variables were tried as predictors of helping. A discomfort index proposed by the U.S. National Weather Service (Mather, 1974, p. 245), which consisted of a weighted multiplicative equation involving temperature and humidity, proved to be negatively related to helping but with a correlation smaller than curvilinear temperature or humidity separately, $r(538) = -.13$, $p < .05$. A wind chill statistic (Mather, 1974, p. 246) that attempted to combine both temperature and wind velocity proved unrelated to helping, $r(538) = .03$, *ns*, perhaps because of the curvilinear relation of temperature to helping. Finally, a statistic proposed by Dirnagl (1977) that combined temperature, humidity, and barometric pressure showed only a modest association with helping, $r(538) = .14$, $p < .01$.

tors was highly significant, multiple $R = .44$, $F(4, 265) = 16.07$, $p < .001$, and accounted for 20% of the variance in helping, with sunshine accounting for 10% of the total variance. In the winter data, sunshine, temperature, and wind velocity were significantly related to helping, whereas humidity, although in the right direction, was not significant. A regression equation with these three significant weather variables was again significant, multiple $R = .49$, $F(3, 266) = 27.44$, $p < .001$, and accounted for 24% of the variance, with sunshine accounting for 16% of the total variance. Lunar phase was significant in neither the summer nor the winter. Further, because of the curvilinear relationship of temperature and interactive relationship of wind velocity with temperature and helping, the partial correlation analysis on the combined sample revealed only sunshine to be significantly associated with helping.

Table 2
Partial Correlations of Selected Weather Variables With Helping

Item	Summer	Winter	Combined
Sunshine	.20***	.28***	.29***
Temperature	−.26***	.26***	−.002

[a] Large value = full moon.
* $p < .05$. ** $p < .01$. *** $p < .001$.

Discussion

This study found significant associations between helping behavior and a number of weather variables. In both zero-order and partial correlation analysis, significant associations were found between sunshine and helping in both seasons, such that helping was greater on bright sunny days compared to cloudy days. In both sets of analyses, helping was greater during periods of cooler temperature and higher wind velocity in the summer, and warmer temperature and lower wind velocity in the winter. Helping was also greater when the relative humidity was lower, although in the partial correlation analyses this association was significant only for the summer data.

The association of lunar phase with helping was ambiguous. While lunar phase was negatively correlated with helping in the zero-order correlations, no association of lunar phase and helping was found in the partial correlations. Since lunar phase was negatively associated with other predictors of helping in this sample—e.g., sunshine and lunar phase, $r(538) = -.29$, $p < .001$—the original correlations may have been spurious.

The association with helping of some of the weather variables, such as wind velocity, temperature, and humidity, might be attributable to the comfort or discomfort that the individuals anticipate experiencing while helping. Being asked to answer some questions when the temperature is low, for example, entails spending additional time in the cold, and that added cost factor could reduce helping.

The comfort interpretation seems less effective as an explanation of the sunshine relationship, however. During Minnesota winters the temperature is often cold while the sky is bright and clear. Considering just those cases where the temperature was below freezing (0 °C) and physical comfort was presumably low, sunshine was still associated with a greater likelihood of helping, $r(177) = .23$, $p < .01$.

The role of comfort in the sunshine–helping relationship might also be examined using the data on the rate at which individuals refused to stop and listen to the interviewer solicit participation. Although this is an ambiguous test of helping because people did not hear all of the request, refusals at least were not based on the length of time outdoors required for helping. Nevertheless, fewer people refused to stop, and thus more were helpful, on sunny days than on cloudy days, $r(122) = -.32$, $p < .01$.

A more direct method for investigating the role of comfort in the association of sunshine and helping would be to use a setting in which comfort factors such as temperature, humidity, and wind velocity could be controlled, whereas sunlight would be free to vary. A dependent variable that does not require a time

commitment would avoid the problem of the linkage between helping and remaining in a positive or negative environment. A follow-up study was thus conducted that examined the effects of weather on the tips left by patrons of an indoor eating establishment.

Experiment 2

Method

Data were gathered from 130 parties dining during the afternoon at a moderately expensive climate-controlled medium-sized restaurant at a shopping center in a western suburb of Chicago. The study was conducted during the afternoon on 13 randomly selected days during the work week in April, May, and June of 1978, and 10 parties were observed each day. The restaurant had windows on two sides, and the temperature ranged from 4° C (40° F) to 27° C (81° F) outdoors and was at 21° C (70° F) indoors.

Six waitresses served to record data, and all were blind to the purposes of the study. On each of the designated days, one waitress was asked to record information about the first 10 parties she waited on after 1:00 p.m. The waitress recorded the number of people in the group, the total amount of the check, the amount of the gratuity, the approximate age and sex of the person or persons leaving the tip, and whether liquor was served. Prior to recording information on the customers, the waitress was asked to record her own mood on a 5-point scale ranging from *good mood* to *bad mood*. Waitresses were carefully instructed in the use of the self-report scale and were asked to be honest, since in a previous study, randomly selected participants were found to be less than adept in using introspective self-report scales (Cunningham, Steinberg, & Grev, in press). For this reason and to avoid becoming intrusive, the moods of the tippers themselves were not assessed.

Weather information was obtained from the National Weather Service, Chicago Forecast Office, and included temperature, barometric pressure, and wind velocity. Sunshine level and lunar phase were obtained as in Study 1.

Table 4
Correlations of Weather and Group Characteristics With Percentage of Check Left As Tip

Results

Since it is customary to leave as a gratuity an amount of money proportional to the size of the check, the principal dependent variable analyzed in this study was the ratio of the amount of money left as a tip to the total bill for the meal. Prior to examining the effect of weather on tipping, the relationship of weather to the status variables age and sex was examined to insure independent sampling.[2] It was found, however, that there was an association between weather and the age and sex of people in the restaurant on a given day. As Table 3 indicates, older people and women were more likely to dine out when the sunshine was bright, the weather was cool, and the humidity, barometric pressure, and wind velocity were high. Although these associations are interesting in their own right, since older people and women also left a more substantial tip than the others, the analysis of the impact of weather on tipping neces-

[2] To insure that variations in tipping were not due to the behavior of individual waitresses, an analysis of variance was conducted, using the six waitresses as independent variables. No effect due to waitresses was found, $F(5, 124) = .025$, *ns*.

arily must take into account this self-selec-ion factor.

Although a regression equation using just he seven weather variables was significant, $F(6, 123) = 4.24$, $p < .01$, two sets of corre-ations are presented in Table 4, the zero-rder correlation between each weather varia-le and tipping and second-order partial orrelations, with the association of age and ex removed from the correlations of weather nd tipping. As Table 4 reveals, despite the act that sunshine was related to an increase n the number of older people and females lining, sunshine was nevertheless significantly elated to helping. This correlation was maller than in Experiment 1, which might e expected, since participants were indoors nd were thus partially screened from effects f the sun.

Although inspection of the zero-order corre-ations suggested some reversals of the find-ngs of Experiment 1 with respect to tempera-ure and humidity, the partial correlations llayed such concerns. As might be expected n a climate-controlled restaurant, outdoor emperature, barometric pressure, and wind elocity had no significant direct effect on ipping. Group size and whether liquor was erved were unrelated to tipping, whereas hu-nidity was marginally correlated. Apparently ontrary to Experiment 1, there was a positive ssociation between the fullness of the moon nd the size of the tip.

Additional partial correlation analyses were erformed to determine the relationship of ach weather variable to tipping, with the ffects of the other weather variables and age nd sex removed. These analyses are pre-ented in Table 5.

Once again, sunshine was significantly cor-elated with tipping. Relative humidity was lso positively correlated with tipping, whereas lunar phase showed a marginal posi-ive association. A regression analysis using unshine, temperature, relative humidity, and unar phase as predictors of tipping produced ignificant associations of sunshine and rela-ive humidity with tipping, $F(4, 125) = 4.73$, $p < .01$, with sunshine accounting for 4% of he total variance.

Table 5
Partial Correlations of Selected Weather Variables With Tipping

Item	Partial *r*

Temperature	.03
Relative humidity	.17**
Lunar phase[a]	.11*

Note. $N = 130$. The effects of age and sex have been partialed out as well as the other weather variables.
[a] Large value = full moon.
* $p < .10$. ** $p < .03$. *** $p < .005$.

To test for a curvilinear relation of temperature with tipping, a weighted equation centered on 19 °C (65 °F) was constructed. Curvilinear temperature was positively related to tipping, $r(128) = .19$, $p < .02$, as a zero-order correlation but was insignificant when the effects of age and sex were removed, $r(128) = .09$.

Examination of the relationship of the weather variables to the self-reported mood of the waitresses, presented in Table 6, provides further insight into the nature of the weather effects. As Table 6 reveals, both sunshine and temperature were significantly related to a more positive mood of the waitress. Waitress mood (obtained prior to the receipt of tips) was not itself a significant predictor of tipping, $r(128) = .004$, suggesting that the effect of weather on tipping may have been mediated by the mental or emotional state of the customers.

Discussion

The second study effectively controlled for the effect on helping of comfort factors such as temperature and wind velocity by investigating the effect of weather on a helping action that did not require the participants to remain outdoors for a period of time in order to be helpful. Nonetheless, this study replicated Experiment 1 by finding that the outdoor sunshine level was significantly related both to the gratuity left for the waitress in a restaurant and to the waitress's self-reported mood.

Of course, the fact that sunshine was associated with both customers' helping and waitresses' mood does not necessarily mean that changes in customers' mood produced the variations in helping. The observed variations in both helping and mood as a function of sunshine could have involved separate mediational mechanisms. Yet because of the strong experimental evidence for an effect of mood on helping (Isen & Levin, 1972; Cunningham, Steinberg, & Grev, in press) and the lack of a plausible alternate mediator for the effect of sunshine on helping, mood seems a prime candidate. The present study did not, however, provide information on how sunshine might affect mood. Explanations based on symbolic associations, aesthetics, and biological processes all seem reasonable.

Sunshine level could influence mood through its symbolic connection with pleasant or disappointing events. Thus sunshine could increase mood by stimulating thoughts of swimming, picnics, and other outings, whereas cloudy days could be associated with the disappointment of canceled plans and the annoyance of rain and snow and could in that way alter the individual's mood.

Alternatively, sunshine could produce a more positive mood by illuminating the environment in a more stimulating and pleasing manner. Clear sunlight has spectral characteristics different from the light on cloudy days and with its stronger intensity may enhance colors and sharpen detail. The scenery on a cloudy day may appear more dull and monochromatic, by contrast. Maslow and Mintz (1956) have demonstrated that the aesthetic quality of indoor settings affected mood and person perception, and sunshine might similarly influence mood primarily through aesthetic responses to the environment.

Sunshine could also influence mood through its effect on physiological processes. There are indications both from experimental studies on light deprivation and clinical studies of blind and cataract patients that the level of light detected may affect adrenal corticosteroid production and other endocrine functions, hemoglobin formation, thyroid activity, the detoxification capacity of the liver, and the overall regulation of circadian and cirannual biorhythms (Luce, 1970). Solar radiation can also increase the atmospheric concentration of negative ions, and increased negative ion concentration has been linked to increased oxidation of serotonin and increased relaxation in humans (Krueger & Reed, 1976; Randall, 1970). Alternately, since cloud cover filters out ultraviolet rays, decreased ultraviolet light may retard physiological processes such as Vitamin D production (Ott, 1973). Yet since no direct measures of blood chemistry were obtained in the present studies, such interpretations of the effect of sunlight, like those based on associations and aesthetics, remain speculative.

The series of studies reported here employed a quasi-experimental correlation design, and the lack of total control over the independent variables produced some ambiguous results. First, in Experiment 2 older people and women were more likely to eat in the restaurant, and thus participate in the study, on sunnier, cooler, windier, more humid, higher pressure days. Although it is believed that statistical control for such self-selection factors was adequate, complete random assignment to conditions would have been more desirable.

Nowhere are the weaknesses of the correlational approach more apparent than in the case of lunar phase effects. In the zero-correlation analysis in Experiment 1, a negative association with helping was found in both seasons, but this relationship disappeared in the partial correlation analysis. Experiment 2 found a significant positive relationship with tipping, although no association was found

with waitresses' mood. Since a recent review of the lunar phase literature pertaining to homicide, suicide, and psychiatric admission frequency (Campbell & Beets, 1978) indicated substantial inconsistency in findings across studies and argued that published significant associations were due to Type I errors, the present small but significant correlations are regarded as somewhat of a nuisance. As with other variables, such as sunshine, employed in this study, a full explanation of proposed effects will require measurement of physical, physiological, and psychological processes influenced by a factor such as the moon. Given the overabundance of speculation concerning the nature of lunar influences, no interpretation of the present findings will be offered.

Two other apparent inconsistencies should be noted. In Experiment 1 humidity was negatively associated with helping, whereas in Experiment 2 the association was positive. This discrepancy is reasonable, however, if one assumes that the higher the outdoor humidity, the more relief the restaurant patron experienced when coming into a climate-controlled environment. Appreciation or more positive mood following such relief could have increased tipping.

Another inconsistency concerns the relationship of temperature with the various dependent measures. Temperature showed an inverted U-shaped relationship with helping in Experiment 1 but was positively related to waitresses' mood in Experiment 2. Yet the positive relation with waitresses' mood is compatible with an overall curvilinear relationship, given the more restricted temperature range of Experiment 2. Temperature was not, however, clearly linearly or curvilinearly related to tipping in Experiment 2. This is not surprising, however, given the climate-controlled environment of the restaurant. Further, although waitresses' mood was recorded when the waitresses first came in to begin their shifts, tipping did not occur until the patrons had been away from the outdoor temperature for some time.

The lack of a substantial relationship of barometric pressure with helping in either study was somewhat unexpected in light of previous research. Yet it is well to bear in mind Piccardi's (1962) observation that simply ascending to the top of a skyscraper involves a pressure change equivalent to that stemming from a tornado. Barometric pressures in Experiment 1 ranged from 29.63 to 30.37 and in Experiment 2 from 29.60 to 30.27, which is an average range, but since data were not gathered during rainy or stormy weather, it is possible that some pressure effects were missed.

Also unexpected was the finding that the consumption of alcohol was not related to tipping, nor was the size of the party, contrary to the results of previous research (Freeman, Walker, Borden, & Latane, 1975). But since the precise amount of alcohol consumed was not recorded, and since it was frequently difficult to determine if one person or the entire group contributed to the tip, few conclusions can be drawn.

Although this series of studies has stressed the role of weather variables in helping, the conclusion should not be drawn that the weather is the only or even the major factor contributing to altruism. The strongest predictor, sunshine level, accounted for only 13% of the helping variance when participants were outdoors and 4% of the variance when people were indoors, leaving a great deal to be accounted for by social and individual difference factors. Yet given its relative neglect in the literature, future investigations might examine the relationship between sunshine and other affect-linked behaviors. Alternative indicators of helpfulness or friendliness, such as people's willingness to start a conversation with a stranger or give to charity, might be examined, as well as negative affect-related behaviors such as reports of crime, marital distress, suicide, initial contact with a psychiatric clinic, and constricted nonverbal behavior (Cunningham, 1977). Given the reported friendliness of Californians, it would also be of interest to examine the friendliness of various cities around the world as a function of the amount of sunlight they receive (cf. Feldman, 1968; Robbins, DeWalt, & Pelto, 1972). And the next time experimental subjects are not

performing as predicted, the laboratory psychologist might look outdoors to see what kind of a day it is.

Divergence of Private Evaluations of Alternatives Prior to a Choice

Paul J. Brounstein
University of Maryland, College Park

Nancy Ostrove
Lake Erie College

Judson Mills
University of Maryland, College Park

In an attempt to reconcile past research based on reactance theory that found convergence of evaluations of alternatives prior to a choice, and research based on choice certainty theory that found divergence, it was proposed that convergence occurs in overtly expressed evaluations but that divergence occurs in private evaluations. According to this interpretation, the freedom to choose a nonpreferred alternative is threatened by the overt expression of a preference that involves commitment but is not threatened by the private holding of a preference. As expected from this interpretation, using the procedure in which Linder and Crane and Linder, Wortman, and Brehm found convergence of overtly expressed evaluations, divergence was found when evaluations were made privately, that is, supposedly without the experimenter being aware of the nature of the evaluations.

Brehm's (1966) theory of psychological reactance has been applied to evaluations of alternatives prior to a choice by Wicklund (1968, 1970), who suggested that a preference for one alternative over another may threaten the freedom to choose the nonpreferred alternative and to reject the preferred alternative. Reactance theory assumes that a threat to a freedom leads to attempts to reassert that freedom. The freedom to choose a nonpreferred alternative can be reasserted by increasing the attractiveness of the nonpreferred alternative relative to the preferred alternative. This change would result in convergence of evaluations of the alternatives.

Elaborating this analysis, Linder and Crane (1970) hypothesized that ratings of the attractiveness of alternatives will converge as a choice approaches. Linder and Crane had female undergraduates rate the desirability of two interviewers after reading brief descriptions of them. Some of the subjects had been led to believe that they would choose which of the two would interview them about highly personal topics following a brief "get-acquainted" period with both potential interviewers. The length of the get-acquainted period was varied. Linder and Crane found that the difference in the ratings, given the two interviewers, was smaller when the choice was expected after a 3-minute get-acquainted period than when the get-acquainted period was expected to last 15 minutes or when no choice was expected.

Linder, Wortman, and Brehm (1971) used a procedure similar to that of Linder and Crane but varied the time to the choice while holding the amount of time in the get-acquainted period constant. Replicating the Linder and Crane effect, they found that the difference in the ratings given the two interviewers was smaller when the time to the

choice was 3 minutes than when it was 10 minutes or when no choice was expected.

The studies by Linder et al. provide evidence of convergence of alternatives prior to a choice. However, it is possible that the convergence occurred not because the freedom to choose the nonpreferred alternative was threatened by the private holding of a preference but rather because it was threatened by the overt expression of a preference that involved commitment. In the studies by Linder et al., the ratings of the alternatives were not completely private but were made with the knowledge that they would be seen by the experimenter. This could have made the subjects feel that expressing a preference for one alternative would commit them to choosing it, for to do otherwise would leave the experimenter with the impression that they were inconsistent or flighty. Such an impression should be expected to be stronger, the shorter the time from the preference to the choice.

The assumption that the overt expression of a preference that involves commitment threatens the person's freedom to choose the nonpreferred alternative, whereas the private holding of a preference does not, provides a means of reconciling the findings of Linder et al. with research by O'Neal and Mills (O'Neal & Mills, 1969; Mills & O'Neal, 1971; O'Neal, 1971) that has provided evidence of divergence in evaluations of alternatives prior to a choice. The research by O'Neal and Mills was based on a theory of choice certainty (Mills, 1968), which assumes that people want to be certain when taking an action that it is better than the other alternatives. Certainty about a prospective choice can be increased by increasing the attractiveness of the preferred alternative relative to the nonpreferred alternative, which would result in divergence of evaluations of the alternatives.

O'Neal and Mills (1969) tested the hypothesis that individuals faced with a choice about other persons will demonstrate a greater halo effect in their impressions of those persons. They found that the anticipation of making a choice about which women in a set of photographs were promiscuous increased the intercorrelation of rankings of the women on desirable traits such as *artistic* and *sincere*. Giving one person consistently high rankings on desirable traits and another consistently low rankings indicates a greater difference in attractiveness than do rankings that are not as consistently high or low. In a follow-up study, Mills and O'Neal (1971) replicated the findings of O'Neal and Mills and showed that they could not be attributed to greater attention paid to the choice photographs.

Using a choice about the subject's partners for a group task, O'Neal (1971) showed that the greater the importance of the anticipated choice, the greater the magnitude of the halo effect. When the prospective choice would definitely determine the subject's partners, it increased the intercorrelation of rankings of the potential partners on desirable traits; but when there was only a small chance that the choice would determine the subject's partners, it did not. O'Neal also found evidence that the influence of an anticipated choice on the halo effect depends on the presence of unexplained arousal. Subjects who were aroused by means of caffeine and were not informed about the source of their arousal showed the effect of anticipated choice on the halo effect, whereas those who were given caffeine and told that it was a stimulant, or those who were given a placebo, did not. The reasoning behind the prediction of this finding was that a lack of certainty about an anticipated choice is typically accompanied by arousal, and when a person anticipating a choice is aroused and does not know the source of his arousal, he may interpret it as resulting from a lack of certainty about the choice, which may have the effect of increasing his desire for certainty.

In the studies by O'Neal and Mills that found divergence in the attractiveness of alternatives prior to a choice, the subjects were not asked to make direct evaluations of the alternatives. Although the rankings of the choice alternatives in those studies were given to the experimenter, they were made on a number of different positive traits and did not, as Wicklund (1974) has noted, involve a bold, blatant discrimination, as in the studies by Linder et al. The assumption that convergence occurs in overtly expressed evaluations of alternatives prior to a choice but that divergence occurs in private evaluations is consistent with the previous research.

The purpose of the present research was to test the interpretation that when evaluations of alternatives involve public commitment, they will converge prior to a choice, but when evaluations do not involve commitment, they will diverge prior to a choice. It was assumed that reactance theory, which predicts convergence in the attractiveness of alternatives prior to a choice, and choice certainty theory, which predicts divergence, are both valid but that predictions of the two theories apply to different circumstances. The prediction of convergence from reactance theory was assumed to apply when there is an overt expression of a preference that involves commitment, and the prediction of divergence from choice certainty theory was assumed to apply when evaluations of the alternatives are private.

Experiment 1

The first study was designed to vary the anticipation of a choice and whether evaluations of the alternatives were public or private, while paralleling the procedure of Linder et al. as closely as possible. A predecision condition, similar to their 3-minute predecision condition, and a no decision condition, the same as their no decision condition, were included. The procedure of Linder et al. was modified slightly so that a private assessment condition, in which the subjects would think that their evaluations would not be known by the experimenter, could be included as well as a public assessment condition, similar to the assessment procedure Linder et al. used. In addition to the same direct assessment of the desirability of the two interviewers used by Linder et al., the subjects were asked to indicate how applicable a number of positive traits were to the interviewers.

In the only other change from the procedure used by Linder et al., the instructions concerning the get-acquainted period with both interviewers were omitted. It was thought that the expectation of meeting the two interviewers would have the effect of minimizing changes in the attractiveness of the interviewers. Research by Walster, Berscheid, and Barclay (1967) has shown that changes in the attractiveness of an alternative are attenuated by the expectation that objective information about that alternative will be forthcoming. In addition, if information that might increase certainty about the choice were expected, there would be less need for the subjects to increase their certainty by changing their evaluations of the alternatives. The instructions concerning the get-acquainted period were not discussed by Linder et al. in relation to the arousal of reactance, and there seemed no reason why the amount of reactance should be affected by the omission of the get-acquainted period.

Method

The subjects were 80 female students in introductory psychology who volunteered, knowing that they would earn extra credit toward their course grades. An equal number was randomly assigned to each of the four experimental conditions: predecision–public assessment, no decision–public assessment, predecision–private assessment, no decision–private assessment. Within each of the four conditions, half of the subjects were run by a female experimenter and half by a male experimenter.

When the subject arrived, she was shown to the experimental room and was given the same instructions concerning the National Foundation for Opinion Research as in the studies by Linder et al. Subjects in the predecision conditions were told that they would be interviewed concerning personal matters ranging from dating patterns and social regulations to their views on sex and that they would be able to choose the interviewer from two graduate students in clinical psychology who had both been judged satisfactory in terms of technique but who differed in their personality characteristics. Subjects in the no decision conditions were told that they would not be interviewed but were being asked to read written descriptions of two interviewers in order to determine the effects of the descriptions. All subjects read the same personality sketches about the two interviewers, Carter and Williams, used by Linder et al.

Afterwards, in a departure from the procedure used by Linder et al., the subject was seated in front of an impressive-looking apparatus previously employed in studies using the Bogus Pipeline (Jones & Sigall, 1971), with the explanation that it was a part of a new measurement technique about which they would like her opinions. The subject was told that when the machine was on, it was hooked up to a central information bank that automatically recorded responses made by turning a dial. The experimenter showed the subject how the dial controlled the movement of a needle on a scale marked from 0 to 30.

Mentioning that he/she would turn on the machine, the experimenter flicked the "on" switch and a loud clattering noise emanated from the apparatus.

Table 1
Means of the Absolute Difference in the Ratings for Experiment I

Assessment	Decision condition	
	No decision	Predecision
Public	10.7	7.9
Private	8.1	15.4

Note. $n = 20$ per cell.

Quickly turning the switch to "off," the experimenter remarked with exasperation that there seemed to be a short circuit somewhere and said that the subject could still practice on the machine "to get the feel of it" while the problem was being fixed. As if on the spur of the moment, the experimenter suggested that the subject use her impressions of the two interviewers during the practice session. For subjects in the predecision conditions, the experimenter added that the practice rarely took more than 3 minutes, after which the subject would choose her interviewer.

The subjects in the public assessment conditions were asked to indicate their responses to items read aloud by turning the dial to the appropriate needle reading and reading the number aloud to the experimenter before returning the dial to 0. In clear view of the subject, the experimenter wrote down her responses.

The subjects in the private assessment conditions were asked to indicate their responses to items read aloud just by turning the dial to the appropriate reading and returning it to 0. The experimenter sat behind a partition that blocked the subject's and experimenter's views of one another, supposedly so that the experimenter's presence would not distract the subject. From a dial concealed behind the partition and connected to the subject's dial, the experimenter recorded the subject's responses.

As in the procedure of Linder et al., the subject indicated how much she agreed with the statement, "I would like to have my interview with Mr. Carter" on a scale from 0 (not at all) to 30 (very much) and rated Williams on the same scale. The subject also indicated how well different traits applied to each of the two men on a scale from 0 (extremely uncharacteristic) to 30 (extremely characteristic). The traits were: capable, kind, patient, responsible, sincere, and understanding.

Following the evaluations of the interviewers, the subjects in the predecision conditions were asked if they had already made a choice about their interviewer. Two of the subjects in the predecision–public assessment condition and one in the predecision–private assessment condition said that they had decided previously. The experimenter casually mentioned to all subjects that there was something more to the study and asked if they had any idea what it might be. The response of one person run under the predecision–public assessment condition indicated suspicion about the procedure, and she was not included as a subject. Finally, the true purpose of the experiment was explained, and each subject promised not to discuss it with others.

Results

The absolute value of the difference between the ratings given Carter and Williams was calculated in the same manner as in the studies by Linder et al. Means of the absolute difference in the ratings for the experimental conditions are presented in Table 1. As can be seen from Table 1, when the assessment of the alternatives was public, the results were similar to those obtained in the studies by Linder et al.; the absolute difference in the ratings of Carter and Williams was smaller in the predecision–public assessment condition than in the no decision–public assessment condition. When the assessment of the alternatives was private, the results were reversed; the absolute difference in the ratings was greater in the predecision–private assessment condition than in the no decision–private assessment condition.

An analysis of variance of the absolute difference in the ratings revealed a significant Decision × Assessment interaction, $F(1, 72) = 6.96$, $p < .01$. The main effects for decision and assessment were not significant, nor were any of the effects involving sex of the experimenter. A planned comparison revealed that the difference between the predecision–public assessment condition and the no decision–public assessment condition was not significant. A second planned comparison revealed that the difference between the predecision–private assessment condition and the no decision–private assessment condition was significant, $F(1, 72) = 7.80$, $p < .01$.

An indirect measure of the evaluation of the two interviewers was computed by taking the absolute difference between the sum of the scores given Carter on the six traits and the sum of the scores given Williams on the traits. The results for the indirect measure were in the same direction as for the direct measure; that is, the absolute difference was less in the predecision–public assessment condition than in the no decision–public assessment condition and was greater in the predecision–private

ssessment condition than in the no decision–rivate assessment condition. However, the ifferences between the conditions were not gnificant for the indirect measure.

Discussion

The results of the first study lend support to the proposed interpretation of the research based on reactance theory (Linder & Crane, 1970; Linder, Wortman, & Brehm, 1971) that found evidence of convergence of evaluations of alternatives prior to a choice and the research based on choice certainty theory (Mills & O'Neal, 1971; O'Neal, 1971; O'Neal & Mills, 1969) that found evidence of divergence. The interpretation reconciles the apparently conflicting results of the past research by making the assumption that the reactance theory prediction of convergence applies to the overt expression of a preference that involves commitment, whereas the choice certainty theory prediction of divergence applies to private evaluations of alternatives. As expected from the proposed interpretation, using the procedure in which Linder et al. found convergence of overtly expressed evaluations, divergence was found when evaluations were made privately.

Although the results for the public assessment conditions paralleled the results in the studies by Linder et al., they were not strong enough to be statistically significant. The only substantial change from the procedure of Linder et al. was the dropping of the instructions concerning the get-acquainted period with both interviewers. As mentioned in the introduction, it was thought that the expectation of meeting both interviewers in the get-acquainted period would make it less likely that the subjects would change their evaluations of the interviewers. It was assumed that the instructions about the get-acquainted period did not influence the arousal of reactance.

It is possible that the anticipation of getting more information concerning the alternatives does affect the amount of reactance created by the overt expression of a preference prior to a choice. According to reactance theory, the importance of the freedom that is threatened determines the amount of reactance created by the threat. The freedom to choose the non-preferred alternative and reject the preferred alternative may be more important when additional information about both of the alternatives is expected. If so, then the convergence effect should be stronger when the instructions concerning the get-acquainted period with both interviewers are included.

Experiment 2

The second study was designed to replicate and extend the findings of the first study. The variables manipulated were time to the choice and whether or not additional information was expected, as well as whether evaluations of the alternatives were public or private. In addition, an attempt was made to replicate exactly the procedures of the 10- and 3-minute predecision conditions of Linder, Wortman, and Brehm (1971).

One major prediction was that the reactance effect—that is, convergence in the evaluations of alternatives as time to choice decreases—would occur when the evaluations are public and additional information is expected. From the assumption that when additional information is not anticipated, the importance of the freedom to choose the non-preferred alternative and reject the preferred alternative is reduced, it was predicted that the convergence effect expected from reactance would be reduced when additional information is not expected. It follows that when evaluations of the alternatives are public and the choice close, the absolute difference in the ratings of the alternatives should be smaller when additional information is anticipated than when it is not anticipated.

The other major prediction was that the choice certainty effect—that is, divergence in the evaluations of alternatives as time to choice decreases—would occur when the evaluations are private and additional information is not expected. It was assumed that the expectation of receiving additional information that might increase certainty about the choice would decrease the need to increase certainty through the reevaluation of alternatives. From this assumption it was predicted that the divergence effect would be reduced when additional information was expected. It follows that when evaluations are private and the

choice close, the absolute difference in the ratings of the alternatives should be greater when additional information is not anticipated than when it is anticipated.

Method

The subjects were 100 female undergraduates in introductory psychology who volunteered, knowing that they would receive extra credit toward their course grades. Ten subjects were randomly assigned to each of the eight experimental conditions of a $2 \times 2 \times 2$ factorial design varying time to choice (10 minutes, 3 minutes), information (expected, not expected), and assessment (public, private). Ten subjects were later randomly assigned to each of the two replication conditions.

The procedure was the same as in Experiment 1, with the following exceptions. All subjects were run by a male experimenter, and all were told that they would be interviewed and would be able to choose their interviewer. In the descriptions of the interviewers, the name Carter was changed to Caster.

Half of the subjects in the factorial design were told that they would be able to meet both interviewers in a brief get-acquainted session prior to the choice (information expected), whereas the other half were not so informed (information not expected). Just prior to the ratings of the interviewers, subjects in the 10-minute conditions were told that one of the interviewers was tied up for the next few minutes, whereas subjects in the 3-minute conditions were told that the interviewers should be ready momentarily.

In the 10 minute – information expected conditions the instructions were as follows:

> After the practice trials, when both men are finally available, you'll be able to have your chat with them. This session will last a couple of minutes, so considering the practice, get-acquainted period, and all, you'll be making your final choice of interviewer in approximately 10 minutes.

In the 10 minute – information not expected conditions the instructions were:

> After the practice trials, I'll get everything ready for the interview; that will also take a couple of minutes, so considering the practice and all, you'll be making your choice of interviewer in approximately 10 minutes.

In the 3 minute – information expected conditions the instructions were:

> After the practice trials, you'll be able to have your chat with the two interviewers, which will last a couple of minutes, so considering the practice and the get-acquainted period, you'll be making your choice of interviewer in approximately 3 minutes.

In the 3 minute – information not expected conditions the instructions were:

> After the practice trials, I'll get everything ready for the interview; that will also take a couple of minutes, so considering the practice and all, you'll be making your choice of interviewer in approximately 3 minutes.

After suggesting that the subject use her first impressions of the two interviewers for the practice session, the experimenter went behind the partition and determined from a random assignment list whether the subject's preference ratings were to be assessed under public or private conditions. The instructions for the public and private assessment conditions were the same as in Experiment 1, but in both conditions the experimenter was behind the partition, and the instructions were given by means of a tape recording to eliminate any possibility that the experimenter could influence the subject's responses by the way he administered the dependent measures. The order of the questions concerning Caster and Williams was counterbalanced.

Subjects in the 10-minute and 3-minute replication conditions were given a booklet that was identical to the one used by Linder et al. (except that Carter was changed to Caster). They expected to receive additional information about the choice alternatives, and the segment of the procedure dealing with the measurement device was omitted. The experimenter manipulated the time-to-choice variable in exactly the same manner as in the factorial design. Ratings of the two interviewers were made on questionnaires that were filled out in the presence of the experimenter and were returned directly to him.

After the dependent measures had been collected, subjects in both the factorial design and the replication conditions were asked if they had already made a choice about their interviewer. One subject in each of the four information not expected conditions said that she had decided previously. The experimenter casually mentioned to all subjects that there was something more to the study and asked if they had any idea what it might be. The responses of four persons indicated accurate suspicion about the procedure and they were not included as subjects. One was run under the 3 minute – information not expected – public assessment condition, one under the 10 minute – information expected – private assessment condition, one under the 3 minute – information not expected – private assessment condition, and one under the 10-minute replication condition.

Finally, the true purpose of the experiment was explained, and each subject promised not to discuss it with others.

Results

The means of the absolute difference in the ratings given Caster and Williams for the eight experimental conditions of the factorial

design are presented in Table 2. As can be seen from Table 2, when the assessment of the alternatives was public, the results were similar to those of Linder et al. and the public assessment conditions of Experiment 1; the absolute difference in the ratings was smaller in the 3-minute condition than in the 10-minute condition when additional information was expected and also when it was not expected. Similar results were obtained in the replication conditions; the mean for the 3-minute replication condition was 7.2 and the mean for the 10-minute replication condition was 8.4.

When the assessment of the alternatives was private and additional information was not expected, the results paralleled those of the private assessment conditions of Experiment 1; the absolute difference in the ratings was greater in the 3 minute – information not expected condition than in the 10 minute – information not expected condition. When additional information was expected, there was virtually no difference between the 3-minute and 10-minute conditions.

A $2 \times 2 \times 2$ analysis of variance of the absolute difference in the ratings revealed that the following effects were significant: the main effect of assessment, $F(1, 92) = 5.11$, $p < .05$; the main effect of information, $F(1, 92) = 9.78$, $p < .01$; the interaction between time to choice and assessment, $F(1, 92) = 4.35$, $p < .05$.[1] The major predictions were tested with the use of planned comparisons.

The major prediction from reactance theory was that the absolute difference in the ratings of the alternatives would be less in the 3 minute – information expected – public assessment condition than in the 10 minute – information expected – public assessment condition. This comparison was not significant. The comparison between the 3 minute – information not expected – public assessment condition and the 10 minute – information not expected – public assessment condition was also not significant. The two 3 minute – public assessment conditions were contrasted with the two 10 minute – public assessment conditions, and the contrast was not significant. The 3-minute replication condition and the 10-minute replication condition were not significantly different. The 3-minute replication condition and the two 3-minute public assessment conditions were contrasted with the 10-minute replication condition and the two 10-minute public assessment conditions. This contrast was also not significant. In addition, the contrast between the 3 minute – information expected – public assessment condition and the 3 minute – information not expected – public assessment condition was not significant.

Table 2
Means of the Absolute Difference in the Ratings for Experiment 2

Assessment	Information	Time to choice: 10 min.	Time to choice: 3 min.
Public	Expected	7.1	5.4
	Not expected	9.5	6.6
Private	Expected	7.0	7.1
	Not expected	10.0	14.9

Note. $n = 10$ per cell.

The major prediction from choice certainty theory was that the absolute difference in the ratings would be greater in the 3 minute – information not expected – private assessment condition than in the 10 minute – information not expected – private assessment condition. This comparison was significant, $F(1, 92) = 4.53$, $p < .05$. As expected, the 3 minute – information not expected – private assessment condition was significantly greater than the 3 minute – information expected – private assessment condition, $F(1, 92) = 11.47$, $p < .01$.

Discussion

The results of the second study fortify the proposed interpretation, which reconciles the

[1] The error term for the analysis of variance and the planned comparisons was derived by pooling the estimate of error from the factorial and replication cells. Exclusion of the replication cells from the error term would not affect the significance levels of any of the comparisons. There would not be any change in the significance levels with exclusion of the four subjects who said they had already made a choice.

apparently conflicting results of the past research (Linder & Crane, 1970; Linder, Wortman, & Brehm, 1971; O'Neal & Mills, 1969; Mills & O'Neal, 1971; O'Neal, 1971) by making the assumption that the reactance theory prediction of convergence of alternatives prior to a choice applies to the overt expression of a preference that involves commitment, whereas the choice certainty theory prediction of divergence applies when evaluations are private. As expected from the proposed interpretation, when preferences were privately assessed and additional information was not expected, the absolute difference in the ratings of the alternatives was greater, the closer the choice. The replication of the divergence effect found in the private assessment conditions of Experiment 1 lends substantial support to part of the proposed interpretation based on choice certainty theory.

That divergence of private evaluations did not occur when additional information was expected is consistent with the choice certainty theory analysis. If additional information is anticipated, there should be little reason to reevaluate the choice alternatives, since the forthcoming information may be sufficient to achieve certainty about which alternative is best. As expected from this reasoning, when evaluations were private and the choice close, the absolute difference in the ratings was greater when additional information was not expected than when it was expected.

The divergence effect that was found in the present research is reminiscent of the divergence that occurs in evaluations of alternatives after a decision (Brehm, 1956). However, there is no basis for regarding the divergence in the present research as postdecisional. It occurred in the private assessment conditions but not in the public assessment conditions, where there was just as much reason, if not more, for subjects already to have made a choice. Also, very few of the subjects in any of the conditions of either Experiment 1 or Experiment 2 said that they had already made a choice.

As in Experiment 1, the results for the public assessment conditions were in the direction of the convergence effect predicted from reactance theory but were not strong enough to be statistically significant. The same was true for the results for the replication conditions, which duplicated as closely as possible the 3-minute and 10-minute conditions of Linder, Wortman, and Brehm (1971).

It is not clear why the convergence effect was not stronger in the present research. The possibility that the lack of a stronger convergence effect in Experiment 1 was due to the omission of the get-acquainted session with both interviewers—which might have reduced the importance of the freedom to choose the nonpreferred alternative—was not borne out by the results of Experiment 2. The tendency for the alternatives to converge in the public assessment conditions was not stronger when the get-acquainted session was included (information expected conditions) than when it was omitted (information not expected conditions).

The fact that the data from the public assessment conditions and the replication conditions were consistently in the predicted direction, together with the significant differences found previously by Linder et al., makes it reasonable to conclude that the convergence effect predicted from reactance theory is reliable. Since it occurs when preferences are public but not when they are private, it can also be concluded that the freedom to choose the nonpreferred alternative and to reject the preferred alternative is threatened by the overt expression of a preference that involves commitment but is not threatened by the private holding of a preference.

Corrections to DePaulo, Rosenthal, Eisenstat, Rogers, and Finkelstein

In the article "Decoding Discrepant Nonverbal Cues" by Bella M. DePaulo, Robert Rosenthal, Russell A. Eisenstat, Peter L. Rogers, and Susan Finkelstein (*Journal of Personality and Social Psychology*, 1978, Vol. 36, No. 3, pp. 313–323), the second, third, and fourth full paragraphs in the left-hand column of p. 320 (starting with "A two-way ANOVA . . .") should be changed to read as follows:

"For the three samples, t tests were computed comparing video primacy for the scenes differing on one affective dimension (slightly discrepant) versus the scenes differing on both affective dimensions (very discrepant). As predicted, there was (slightly) less video primacy (more audio primacy) for the very discrepant scenes than for the slightly discrepant scenes, combined $p = .085$, median $d = .19$."

In addition, the next-to-last sentence in the second full paragraph in the right-hand column of p. 320 should be changed to read:

"However, they were characterized by varying degrees of discrepancy, and subjects tended to attend more to audio cues on the more discrepant scenes than on the less discrepant ones."

Thus, the predicted effect for degree of discrepancy (i.e., the tendency to show relatively greater audio primacy for more discrepant scenes) was much smaller than originally reported. This effect was not stronger for scenes involving the face than for scenes involving the body. This correction is necessitated by a keypunch error that was discovered after publication.

Consensus Information, Prediction, and Causal Attribution: A Review of the Literature and Issues

Saul M. Kassin
Purdue University

The present review of the literature suggests that it is useful to distinguish between two types of consensus information—normative expectancies (e.g., Jones & McGillis' prior probability concept) and explicit base rates (e.g., Kelley's conception of observed covariation across actors). Normative expectancies, which may be derived from a knowledge of one's own behavior (i.e., the false-consensus effect) or the behavior of others, provide one basis for prediction and causal inference. Explicit, sample-based consensus may also be employed, but under somewhat restrictive conditions: (a) when prior expectations are neutralized and/or (b) when the consensus manipulation is particularly strong, salient, easily translatable, representative of the criterial population, and causally relevant. A number of additional issues are reviewed (e.g., the cognitive strategies by which observers reject base rates), and recommendations for the direction of future research are made.

The attribution literature has recently been inundated with studies aimed at determining whether or not and under what conditions naive observers employ consensus information for predicting and explaining behavioral events. To date some experiments have shown that consensus is a valuable source of information, whereas others have indicated that it is not. This paper will attempt to review and organize the diverse findings and discuss some of the important theoretical issues that have been raised.

Theory

Attribution theories portray the layperson as a perceiver who, in order to understand what caused some form of behavior to occur, actively seeks and utilizes various kinds of information. One of the more intuitively appealing of the proposed relationships is the link between consensus and causal attribution. When an individual behaves differently from others (low consensus), observers are likely to view properties of that individual as having had a causal impact; when an actor behaves in a manner consistent with the performance of others (high consensus), observers are apt to infer that some invariant feature or object in the environment elicited the common reaction.

Heider (1958) illustrated this hypothesis when he suggested that consensus influences attributions about the nature of a percept, the origin of motivation and pleasure, and the causal locus of success and failure. Later attribution theories readily adopted the proposed role of consensus in the inference process. For Kelley (1967), consensus—defined as *observed* covariation across actors (i.e., do other actors in the situation behave similarly) —is one of three criteria for assessing the validity of an environmental attribution, the others being distinctiveness (does the actor's behavior occur only in the presence of a particular entity) and consistency (does the actor behave similarly toward the entity at different times). For temporally consistent behaviors, Kelley (1967, 1973) predicted that

those high in consensus (and/or distinctiveness) are causally attributed to the entity, whereas those low in consensus (and/or distinctiveness) are attributed to the actor. Jones and Davis (1965) conceived of consensus as a prior probability variable: Based on a tacit knowledge of norms, social constraints, and values, observers compare an actor's behavior to the *expected* behavior of others. As such, Jones and Davis predicted that behaviors that are low in their "assumed desirability" are more informative of an actor's attributes than those known to be high in their attractiveness or desirability.

In short, theorists have distinguished between two kinds of consensus information—observers' beliefs about what other people *would do* if they were present and observers' firsthand knowledge of what others in the situation *actually do*. The former case exemplifies Jones and Davis's (1965) prior-probability concept and will be referred to as the perceiver's normative expectancy or "implicit consensus." The latter case corresponds to Kelley's (1967) definition of observed covariation and will be referred to as sample-based or explicit-consensus information.

Observers have thus been portrayed as information processors who are "characteristically normative and nomothetic" (Jones et al., 1972, p. 85) and are acutely sensitive to variations in both assumed and observed consensus. Other subsequent formulations (Weiner, 1974) and theoretical integrations (Ajzen & Fishbein, 1975; Anderson, 1974; Jones & McGillis, 1976) have accepted the role of consensus in the attribution process. Moreover, consensus manipulations have been successfully applied by researchers to affect perceptions of task difficulty (Weiner, Frieze, Kukla, Reed, Rest, & Rosenbaum, 1971) and attributions for emotional disorders (Valins & Nisbett, 1971).

Research: An Overview

The Normative Expectancy

Prior to observing the target actor, perceivers—as members of a social structure with often clearly defined behavioral norms—expect to see certain behaviors performed more frequently than others. These crude (i.e., generalized across classes of actors and situations) expectations serve as an initial basis for predicting the frequency of a given act in the population and the behavior potential of a particular individual. For drawing causal inferences, an unexpected act is conceptually equivalent to a low consensus behavior, whereas an expected event is equivalent to one of high consensus.

Generalized behavioral expectancies. Normative expectancies may be derived first from a knowledge of one's own behavior. Heider (1958) often referred to actors' egocentric tendency to use their own behavior as a normative standard. Specifically, he (and recently Ross, 1977) delineated a two-stage process. First, individuals tend to see their own behaviors as environmentally caused and hence consensual. After all, I choose Brand X over Brand Y because Brand X is better; since Brand X is better, most people (would) also choose it. In the second stage, observers who know their own behavior interpret another actor's discrepant performance as low in consensus and attributable to personal causes.

The effects of self-generated consensus have been amply demonstrated. Hansen and Donoghue (1977) had subjects sample a beverage and then watch a confederate who drank either a similar amount or more. In addition to inferring population performance from their own behavior, subjects attributed the other actor's similar performance to the beverage and dissimilar behavior to the actor. Ross et al. (1977) conducted an analogous questionnaire study in which subjects read brief stories of events culminating in a behavioral choice. As it turned out, subjects' own stated choices were related to their estimates of how others would behave. In fact, subjects made more confident and extreme trait ratings to characterize the typical person who would elect the alternative option than to describe the typical person making the same behavioral choice.[1]

Certainly an individual need not actually observe his or her own behavior in order to draw normative inferences. Implicit consensus

[1] Note that these demonstrations of the false-consensus effect are confounded with subject self-selection.

may be generated through a simple knowledge of the population base rates for certain behaviors. In some studies, behaviors that were low in their attractiveness or assumed desirability induced dispositional inferences about the target actors (Ajzen, 1971; Jones, Davis, & Gergen, 1961). In view of the strong correspondence between assumed desirability and perceived probability of occurrence (Ajzen, 1971; Eisen, Note 1), these studies indirectly support the normative expectancy–causal attribution hypothesis. In other studies, Lay, Burron, and Jackson (1973) and Kassin and Lowe (in press) actually pretested the base rates and perceived base rates for stimulus behaviors, respectively. Lay et al. (1973), for example, found that subjects made more confident inferences about the traits of a person who supposedly endorsed a low base-rate item (e.g., "I joke and talk rather than work whenever possible") than about one who endorsed a high base-rate item (e.g., "I love to tell and listen to jokes and funny stories").

Actor-based expectancies. Of course, behavioral expectancies are often refined by an observer's knowledge about characteristics of the target actor (e.g., sex, age, occupation). Jones and McGillis (1976) described actor-based expectancies as follows: "Category membership suggests a modal behavior expectancy or the presence of one categorizing feature (obesity) suggests other correlated features (jolliness)" (p. 413). Kahneman and Tversky (1973), for example, capitalized on popular stereotypes about occupations. In the well-known engineer–lawyer study, they told one group of subjects that a sample contained 70% lawyers and 30% engineers, whereas another group was presented with a sample of 30% lawyers and 70% engineers. Subjects then read descriptions of five target individuals taken from that group and predicted the likelihood that each person was a lawyer (engineer). One description read:

> Jack is a 45-year-old man. He is married and has four children. He is generally conservative, careful, and ambitious. He shows no interest in political and social issues and spends most of his free time on his many hobbies which include home carpentry, sailing, and mathematical puzzles. (p. 241)

Results indicated that subjects underutilized the 70–30 base rates and relied largely on the personality-stereotypic cues (e.g., classifying the individual as an engineer if he shows no interest in political and social issues, enjoys mathematical puzzles, and so on). Since this study, observers' reliance on brief personality sketches for making *category* predictions has been repeatedly demonstrated (e.g., Zuckerman, 1978a).

Predictions about *behavior* are similarly influenced by actor-based expectancies. For example, Miller, Gillen, Schenker, and Radlove (1974) had subjects read about Milgram's (1963) obedience study and then guess how selected stimulus persons responded. They found that the target person's sex and attractiveness affected this measure—subjects predicted that males and unattractive individuals would administer greater levels of shock than females and physically attractive participants would.

Situation-based expectancies. Normative expectancies may also be qualified by situational demands (Herzberger, in press; Jones et al., 1961; Jones & McGillis, 1976). Lowe and Kassin (1977) manipulated the implicit consensus for helping behavior by altering several factors of the described situation (e.g., the personality and appearance of the requester). For subjects who were not presented with the base rates for helping, population estimates were as anticipated: 67% (high implicit consensus), 44% (moderate implicit consensus), and 37% (low implicit consensus). More importantly, causal attribution and trait inference followed from these estimates—subjects evaluated a nonhelping actor more negatively when helping was expected. Others have noted similar effects. Miller et al. (1974) found that Milgram's obedience study elicited clear nonobedience expectations. Nisbett and Borgida (1975) reported that their subjects expected helping behavior in the Darley and Latané (1968) seizure study.

Summary. In sum, it appears that normative expectancies that are based on previous self- and other-observation provide an initial basis for prediction and attribution. To a large extent, these expectations are actor specific (e.g., "males are generally more aggressive than females") and situation specific

(e.g., "people are generally not aggressive in school"). When information about the actor and/or situation is unavailable or uninformative, then observers may fall back on normative expectancies that are more generalized (e.g., "People are generally [not] aggressive").

Explicit Consensus

Explicit consensus refers to the *actual* behavior of individuals in a sample. Early tests of Kelley's (1967) model supported the consensus–attribution hypothesis (Frieze & Weiner, 1971; McArthur, 1972). In the prototypical study, McArthur (1972) presented subjects with behavioral descriptions (e.g., "John laughs at the comedian") to which high or low consensus, distinctiveness, and consistency were appended. Consensus information took the form "almost everyone (hardly anyone) else laughed at the comedian" and was utilized as predicted toward person attribution and especially toward stimulus attribution. In subsequent experimentation, Orvis, Cunningham, and Kelley (1975) found that knowledge of consensus was sufficient for subjects to "figure out" the distinctiveness and consistency of an event—high and low consensus induced inferences of high consistency as well as high and low distinctiveness, respectively.

Finally, two somewhat established empirical patterns are noteworthy. First, explicit consensus appears to be particularly informative about the *stimulus* in a situation (Orvis et al., 1975; McArthur, 1976; Zuckerman, 1978b). Subjects given a stimulus attribution for fictitious events readily infer high consensus (Zuckerman & Mann, in press), solicit consensus more than any other kind of information (Garland, Hardy, & Stephenson, 1975), and rank it as the most important variable governing these decisions (Vestewig, Note 2). Developmentally, the high consensus – stimulus inference relationship precedes the link between low consensus and person inferences (DiVitto & McArthur, 1978). Second, a growing body of evidence suggests that perhaps *observers* make better use of consensus information than do actors, who tend to rely more heavily on distinctiveness (Hansen, 1976; Hansen & Lowe, 1976) or on a knowledge of their own previous behavior (Hansen & Donoghue, 1977; Hansen & Stonner, 1978).

Despite the findings cited above, certain recent developments in the literature have cast some doubt as to whether observers are as sensitive to consensus as was initially believed. Within the attribution area, McArthur (1972) noted that although main effects for consensus on attributions were obtained, it was the least effective of Kelley's three variables. This conclusion about the *relative* ineffectiveness of consensus was extended to issues such as developmental trends in the use of Kelley's variables (DiVitto & McArthur, 1978; Dix, Herzberger, & Erlebacher, Note 3; Karlovac, Feldman, Higgins, & Ruble, Note 4; Swann & Collins, Note 5) and has been widely cited as evidence for the absolute ineffectiveness of consensus.

In the social judgment literature, analogous deficiencies in observers' use of base rates toward prediction have been reported (e.g., the Kahneman & Tversky, 1973, studies). On the one hand, the apparent comparability of results between the attribution (e.g., Nisbett & Borgida, 1975) and judgment (e.g., Kahneman & Tversky, 1973) studies is impressive in view of their contrasting research paradigms (for an excellent discussion, see Fischhoff, 1976). On the other hand, one must be cognizant of the vastly different conclusions that follow from the fact that researchers in the two disciplines pose somewhat different questions. Attribution researchers make the traditional comparison between subjects' responses and the null hypothesis (i.e., does consensus influence inferences, or is it ignored?), whereas the social judgment investigators compare subjects' predictions with those implied by a formal probability model (i.e., do subjects make optimal or suboptimal use of the base rate? see Borgida, 1978; Wells & Harvey, 1978).

Citing the McArthur (1972) and Kahneman and Tversky (1973) experiments, Nisbett and his colleagues performed a number of experiments in which some subjects but not others received base-rate information. No differences in their dependent measures emerged, leading the authors to conclude

hat perceivers ignore consensus. Because of he importance of this research, two studies in particular will be described.

Nisbett and Borgida (1975) presented subjects with descriptions of two experimental situations: the high fear condition of a shock tolerance study (Nisbett & Schachter, 1966) and the emergency condition of a bystander intervention study (Darley & Latané, 1968). Consensus–information subjects read frequency distribution tables indicating that most participants in the shock study tolerated a large degree of shock and that most participants in the helping study either took a long time to help or did not help at all. No consensus–information subjects did not read about these results. In one study, subjects read brief descriptions of participants and guessed how these target actors had behaved. In a second study, subjects were told that the described actors behaved in the extreme, high base-rate manner (i.e., tolerated maximum shock, did not help). They then rated that participant on a number of relevant traits and indicated whether that behavior was personally or situationally caused. Overall, knowledge of base rates had no effect on prediction, attribution, or trait inference.

In another study, Nisbett et al. (1976) failed in three attempts to mitigate depression with the use of high-consensus information that was designed to externalize the perceived cause of the affect, thereby reducing worry. One study that dealt with the "Sunday blues" illustrates their general approach. Male undergraduates filled out a number of mood scales, a questionnaire reporting on their academic and social activities for the day, and rating scales for cartoon funniness. After these initial Sunday premeasures, one group received statistics showing that many students experience the Sunday blues (92% occasionally, 65% often), a second group was provided with an explanation of the phenomenon to supplement this consensus, and a third group was not given any base-rate information. Postmanipulation measures revealed that no changes in mood took place in any of the groups, including those presented with the consensus.

Research since these influential experiments has focused on determining those conditions that mediate the efficacy of explicit consensus. One outcome of the more recent work in this area is the widespread recognition that the interaction between expectancies and sample-based consensus is important and that the consensus–attribution relationship is a complex one whose boundary conditions are easily violated. What has thus far emerged is a collection of empirical findings and issues that suggests the following modest proposition: Any conclusions about the effects of consensus information must be qualified—by stating what kind of consensus manipulation (e.g., implicit or explicit, concretely or abstractly presented), what kind of effect (i.e., individual or population prediction, causal attribution, trait inference), and compared to what response criterion (i.e., the null hypothesis vs. a normative model).

Normative Expectancies Versus Explicit Consensus

The Consistency Problem

Self-generated consensus appears to provide a powerful frame of reference, one that may be based upon a lifetime of self- and other-observation. Some investigators have thus suggested that experimental consensus manipulations might be ineffective because of interference from prior expectations. After all, subjects are typically presented with base rates about a target behavior that in itself arouses normative expectations. Additionally, subjects may observe or read about the surrounding situation, the target stimulus, and/or the target actor, all of which contribute to this prior belief. In other words, sample base rates often comprise only one source of consensus information.

In cases where an observer is confronted with base rates for a behavior that is high or low in implicit consensus, the degree of consistency–inconsistency between the two could partly determine the efficacy of the manipulated (i.e., explicit) consensus. At one extreme, the impact of base rates (i.e., relative to a no-base-rate control) may be minimal if they are *redundant* with prior expectations. In this regard, Wells and Harvey (1977) noted that Nisbett et al. (1976) probably

presented subjects with a redundant and hence uninformative consensus manipulation. Recall that these latter investigators sought to mitigate depressive moods with the use of high-consensus information. Nisbett et al. (1976) noted that the Sunday blues are commonly experienced by students; yet perhaps subjects were also aware that this negative affect was normative. Although the no consensus subjects' prior beliefs were not assessed, their estimates might not have differed from those of the base-rate subjects. In other words, perhaps the manipulation was uninformative, having little effect on already existing beliefs.

A more common problem arises when base rates are rejected for being highly *discrepant* with implicit consensus. Instances of extreme inconsistency are fairly well documented. Nisbett and Borgida (1975) noted this kind of discrepancy in their study when they compared the "naive estimates" made by the no base-rate subjects (i.e., extreme shock tolerance/not helping a victim were unexpected behaviors) with the base rates actually presented (i.e., shock tolerance/nonhelping were high-consensus behaviors). Miller et al. (1974) presented their subjects with the surprising results of Milgram's (1963) obedience study and also found that subjects did not employ the consensus for prediction or explanation. Finally, Kahneman and Tversky (1973) reported that base rates had little effect on category prediction when they conflicted with the expectancies aroused by their target-case descriptions.

In sum, it appears that observers' use of sample-based consensus is minimal when this information is highly redundant or discrepant with baseline expectancies. We turn now to discussions about the cognitive strategies by which individuals reject discrepant base rates and the ways in which the effectiveness of explicit consensus has been increased.

Cognitive Strategies for the Rejection of Explicit Consensus

If observers do indeed reject base rates that are inconsistent with their beliefs, what are the cognitive strategies by which they reject the new information? One possibility is that the perceiver may simply disbelieve the base rate. Results of a survey sponsored by a political party as well as the manipulations of a psychology experimenter may thus be dismissed as false and deceptive. More important, however, are those situations where the observed consensus is *believed* but is rejected as uninformative.

The first mechanism that comes to mind is the possibility for distorted recall. Perhaps subjects who read that very few participants helped a seizure victim actually recalled a higher base rate immediately prior to their dependent variable responses. This possibility is ruled out by consensus recall results (Nisbett & Borgida, 1975; Wells & Harvey, 1977), which held up even when manipulation and assessment were separated in time (Nisbett & Borgida, 1975). Wells and Harvey (1977) did identify one strategy typically employed by observers who are confronted with discrepant base rates. Subjects—either informed or uninformed of sample randomness—read the bystander intervention study and base rates indicating that helping was either high or low in consensus. They then indicated the extent to which the participants comprising the base rate were "representative" and "different" from students in general. In the no-knowledge-of-randomness condition, the lower the base rates for helping were, the more different from people in general that sample of actors was rated. Having been presented with highly unexpected information, subjects readily assumed a *bias* in the observed sample as a means of rejecting the base rate as uninformative of the "true" consensus.

What about observers' inferences about the *size* of a sample? Kahneman and Tversky (1972) asserted that "people often take seriously a result stated in percentages, with no concern for the number of observations, which may be ridiculously small" (p. 44). Wells and Harvey's (1977) findings, however, suggest a second mechanism that perceivers might invoke when confronted with a discrepant *percentage*—to infer that it was based on a small sample. Accordingly, Kassin (1979) had subjects read one of two situations in which helping behavior was either expected or unexpected and results indicating either a high

or low base-rate percentage. As predicted, expectancies and base rates interacted—subjects for whom the consensus percentages were discrepant with normative expectations (i.e., high expectancy, low base rate and low expectancy, high base rate) assumed that the consensus had been derived from a small sample. In sum, observers have at their disposal certain mechanisms with which they justify their dismissal of sample-based consensus information.

Effective Manipulations of Explicit Consensus

In view of the problems associated with highly discrepant or redundant consensus information, it is not surprising that significant effects for sample-based consensus have generally been obtained under somewhat restrictive conditions—either when the manipulation is strengthened (e.g., when it is particularly salient) or when normative expectancies have been neutralized (i.e., in the absence of information about the target actor and stimulus). What follows now is a review of those conditions that have successfully increased observers' use of base rates.

Neutralization of Expectancies

A number of investigators have obtained strong effects for sample-based consensus by denying subjects access to expectancy-arousing information. For example, Kassin and Lowe (Note 6) conducted two experiments in which consensus and distinctiveness information were illustrated through the movement of objects (after Heider & Simmel, 1944). Specifically, a series of animated films was shown depicting interactions between three triangles (Target Persons A, B, C) and three squares (Target Stimuli X, Y, Z). In one experiment, Target Actor B bumped Target Stimulus Y. For high consensus, Persons A and C also bumped Y; for low consensus, A and C approached but did not bump Y. Distinctiveness was similarly operationalized by varying the behavior of Actor B toward the other stimuli, X and Z. In contrast to some previous findings, consensus had a large effect on causal attribution and was often cited by subjects in their free response explanations; it also had a particularly strong effect on predictions about the target stimulus.

Hansen and Lowe (1976), who manipulated consensus by having observers view actors' bogus reactions to musical stimuli, also insured control over expectancies—by pretesting the stimuli and selecting those that had been rated as neutral and equivalent. In this way, observers' tendencies to infer high consensus from their own preferences (Hansen & Donoghue, 1977; Ross et al., 1977) were minimized. Finally, the study by Feldman, Higgins, Karlovac, and Ruble (1976) is particularly informative of this boundary condition for an explicit-consensus effect. Consensus was presented in videotaped sequences of an actor making a choice among items and others either agreeing or disagreeing with that choice. As it turned out, causal attributions were influenced by the manipulation, but only for subjects who did not actually see the stimuli from which the actor's choice was made. Of course, instances where base rates influence target-case prediction only when individuating information is unavailable (Carroll & Siegler, 1977; Kahneman & Tversky, 1973; Zuckerman, 1978a) reflect the same pattern. In fact, both Kahneman and Tversky (1973) and Zuckerman (1978a) found that the impact of base rates on target prediction was consistently greater for subjects who did not read a description of the stimulus person than for those who did.

Factors That Strengthen Consensus

Clearly, most of the recent research effort has been directed toward isolating those conditions that strengthen manipulations of explicit consensus. These factors are reviewed below.

Magnitude of Consensus

How high is high consensus? Because consensus refers to a *proportion*, one obvious prediction is that the stronger the consensus manipulation (e.g., 90%–10% rather than 60%–40%), the greater will be its effect on predictions and causal inferences. In McArthur's (1972) and other similar question-

naire experiments, the actual proportions were not specified. For those presentations of consensus in which subjects directly viewed the behavior of others, the three (Hansen & Lowe, 1976) or four (Feldman et al., 1976) others behaved unanimously, thereby creating small-sample base rates of 100%–25% and 100%–20%, respectively. Only since the Nisbett and Borgida experiments (1975) have attribution researchers begun to present their subjects with more complex base rates composed of larger samples of "others." Wells and Harvey (1977) suggested that Nisbett and Borgida's (1975) base rate manipulations were relatively weak. Experiments were thus conducted in which the same two situations were described but with a lower low consensus and a higher high consensus added. As predicted, the stronger version of consensus had a somewhat greater effect than did the original manipulation (see also Smith, Note 7).

Salience or Availability of the Base Rate

Consensus is not necessarily an abstract form of information. Rather, manipulations of sample-based consensus may vary along a continuum of salience and concreteness. At one extreme, it may be operationalized as a "remote, pallid, and abstract" (Nisbett et al., 1976) summary base rate. At the other extreme, consensus information may be conveyed more concretely—through the live or videotaped actions of others (e.g., Feldman et al., 1976) or through the animated movements of objects (Kassin & Lowe, Note 6). Borgida and Nisbett (1977) have argued convincingly that concrete information is more compelling than similar information presented in abstract form. To the extent that perceivers successively consider possible causes in order of their salience (Smith, Note 7), consensus-based inference may be facilitated by factors that increase the variable's attention value and perhaps its availability for recall (Taylor & Fiske, 1978).

Sequential versus simultaneous presentation. As with other variables in social perception, consensus often unfolds over time. Recall that Feldman et al. (1976) manipulated the consensus of an actor's choice. In a simultaneous-presentation condition, the four other actors then agreed or disagreed with this choice in unison; in a serial-presentation condition, four other actors then agreed or disagreed individually. A Consensus × Mode of Presentation interaction indicated that consensus affected causal attributions more when it was presented sequentially than when it was presented simultaneously. In fact, a comparable study (reported by Manis, 1977) has revealed that subjects' use of base rates for making categorical *predictions* is also increased by a sequential mode of presentation. Feldman et al. (1976) explained this effect as "a tendency for subjects to process simultaneous information as a single bit of information, but process successive information as independent bits of information. Thus, there would be 'more' consensus information processed by subjects in the successive presentation condition" (p. 697). The importance of these findings is underscored by their ecological validity. Since consensus information in "real-world," nonlaboratory settings is often acquired through multiple observations that are separated by time, it is probably a powerful determinant of prediction and attribution.

Order of information presentation. The recognized importance of temporal factors has stimulated a number of interesting hypotheses concerning the *order* of information presentation at three levels: Between consensus and other cues, between the target actor versus others' behavior, and within the others' behavior. At the first level, Ruble and Feldman (1976) varied the order in which consensus, distinctiveness, and consistency were presented in a questionnaire study and found a recency effect—high versus low consensus had the least impact when presented first and the greatest impact when presented last (see also Zuckerman, 1978b). The relative strengths of consensus and distinctiveness may thus be vulnerable to the order of information presentation.

The order in which the target actor versus the others' behavior is viewed is also an important characteristic of consensus when its perception is embedded in time. In the videotapes of Feldman et al. (1976), the target actor always made a choice before rather than after the others did. On the assumption that

observers are attuned to conformity and compliance cues, Kassin (1977) varied the consensus and order of behavior in a contrived aggression experiment and found that an actor's high-consensus aggression was personally attributed less often when he delivered shock after the others did than when he did so before the others. Thus, the order of the target and others' behavior may mediate the consensus effect, at least for behaviors that entail social pressure and when the order is not fixed by social constraints (e.g., "respond when you decide" rather than "respond in order of seating").

Finally at the third level, there is ample evidence from research in impression formation (Jones & Goethals, 1971) to suggest that the order in which the others' behaviors appear might actually elicit differential *estimates* of consensus (e.g., One's estimate that "most actors choose X over 0" could vary if the choices unfold as xxxxx00, 00xxxxx, or xx0xx0x).

Translatability of the base rate. Carroll and Siegler (1977) suggested that perhaps Kahneman and Tversky's (1973) subjects viewed the category base rates as relevant but had difficulty drawing a direct implication from them. Specifically, they noted, "if they attempt to probability match (cf. Weir, 1964), there would be no direct correspondence between a 70%/30% division in the population and how a sample of five people can be divided. Seeing no direct solution to the problem of how to use the base rate information, subjects may then decide to ignore it" (p. 393). Accordingly, Carroll and Siegler (1977) examined the effect of translatability on base-rate utilization.

In that study (reported Experiment 2), half the subjects predicted the occupations of 10 individuals sampled from a population of 20 with a 70%–30% base rate (these figures afforded direct translation into a 7–3 partition for the 10-member sample). The other subjects were presented with base rates that were 75%–25% and hence did not allow for whole number translation to a sample of 10. Results indicated that despite the increased strength of the consensus manipulation in the latter condition, predictions were influenced only by the translatable base rates. A similar effect was reported by Tversky and Kahneman (1974), who labeled this availability heuristic "imaginability." Thus, the ease with which a base rate may be applied to a prediction task affects subjects' use of the information.

Representativeness of the Sample

Of perhaps even greater importance than the salience or availability of explicit consensus is its perceived validity. One severe limitation of explicit consensus is that it is based on the observation of a limited sample. Thus, although the sample base rates should always influence guesses about the behavior of persons from that group, utilization of these data toward prediction of other samples or the population at large is necessarily constrained by the perceived representativeness of the original sample. This limitation was demonstrated in studies showing that base-rate information may be undermined by inferences that the sample is biased (Wells & Harvey, 1977) or small (Kassin, 1979).

Knowledge of randomness. One variable that enhances the meaningfulness of a base rate is knowledge of random selection. Theoretically, consensus utilization requires a belief that the observed sample of actors is representative of the population (see Wells & Harvey, 1978). In line with Kelley's (1967) model, a consensual behavior should be situationally attributed. However, this inference may be undermined by a perceiver's dismissal of the base rate as being attributable to some idiosyncratic characteristics of the observed sample. For example, if all the actors in a group solve a puzzle, an observer may not infer task ease if he or she believes that the individuals are geniuses. The perceiver must know or be able to assume that the actors are representative of the population, and hence of average intellect, in order to make the appropriate inferences.

Wells and Harvey (1977) dealt extensively with this issue. Noting that Nisbett and Borgida's (1975) subjects might have assumed that the base rate sample was biased, Wells and Harvey told half of their subjects that the samples from which the base rates were derived had been randomly selected. Sure

enough, percentage estimates of population performance and causal attributions for the behavior of another were influenced by consensus only for subjects in the knowledge-of-random-sampling condition, a finding corroborated by Hansen and Donoghue (1977). Guesses about the behavior of persons who were in the original sample, however, were affected by consensus with and without the randomness variation. Consistent, then, with the notion that knowledge of randomness increases the generalizability of a base rate to *new* samples, such instructions affected extra-sample prediction (i.e., the prediction of individuals in the general population) but not intrasample guesses (i.e., guessing the behavior of target actors from the original sample).

An intriguing and related side issue concerns the "others" comprising consensus. Kahneman and Tversky (1973) insisted that people are more confident when making inferences from correlated than from independent cues. However, Goethals (1972) found that an actor's confidence is increased more by agreement with a dissimilar other than with a similar other, tentatively suggesting that high consensus is more informative about a stimulus when there is variability in the personal characteristics of the actors in a sample. Finally, note that Borgida (1978) proposed an additional, more concrete method by which to convey representativeness information—to show subjects a few "typical" people from the sample who behaved consensually.

Sample size. Ajzen and Fishbein (1975) suggested that when a proportion is held constant, information gain and hence causal attribution should increase with sample size, that is, with the number of observed events. The fact that "30 out of 40 students failed the exam" should thus provide more information than would "3 out of 4 students failed the exam." Accordingly, Kassin (1979) presented subjects with a description of a helping experiment and two conflicting sets of results—one derived from a sample of 10 actors and the other from a sample of 50. For some subjects, helping was high in base rates for the large sample, (60%, 70%, 80%, *or* 90%) and low in base rate for the small sample (40%, 30%, 20%, *or* 10%, respectively). For others, the base rates were conversely low for the large sample and high in the small sample. Results for both individual and population predictions indicated that although subjects did not make "optimal" use of the information (i.e., a weighted average), they did demonstrate an overall reliance on the larger-sample base rate.

Causal Relevance of Consensus

Base rates with an explanation. On the premise that people possess and often invoke their intuitive theories about the causes of events, Ajzen (1977) proposed that "causality heuristics" mediate the consensus–prediction relationship:

> When asked to make a prediction, people look for factors that would cause the behavior or event under consideration. Information that provides evidence concerning the presence or absence of such causal factors is therefore likely to influence predictions. Other items of information, even though important by the normative principles of statistical prediction, will tend to be neglected if they have no apparent causal significance. Statistical information is used mainly when no causal information is available. (p. 304)

To test this proposition, Ajzen (1977) had subjects predict fictitious students' academic success (i.e., grade point average) from two cues—one that was intuitively causal (IQ or study time) and one that was not (income or distance from campus). In addition, he told subjects that each cue had demonstrated either a strong or weak relationship to the criterion. Results indicated that subjects' predictions were influenced more by causal and empirically strong cues than by noncausal and weak cues, respectively. More important, the causal nature of the information had a greater impact than did its empirical validity. In fact, the causal–weak cue was given greater weight than the noncausal–strong cue (e.g., even when IQ was a weak predictor and distance was strong, IQ weighed more heavily in subjects' decisions). Within the framework of these results, Ajzen explained subjects' underutilization of base rates in Kahneman and Tversky's (1973) lawyer–engineer study by noting that the proportion of lawyers (engi-

neers) did not *cause* any member of the sample to become an engineer or lawyer, whereas the target–case description did provide such causal information.

By way of implication, one way to increase observers' use of base rates is to augment them with a reasonable explanation or "causal theory." Smith (Note 7) presented subjects with the bystander intervention and shock tolerance descriptions employed by Nisbett and Borgida (1975). In addition to the standard high- and no-base-rate groups, others were provided with supplementary explanations (e.g., "74% went all the way to the last shock because they were low in anxiety" or "because they wanted the experimenter to approve of them"). Sure enough, this manipulation increased subjects' use of the consensus toward individual prediction, leading the author to conclude that "the reason becomes salient as a possible cause of behavior" (p. 24). Finally, note that Tversky and Kahneman (1978) have also conceptualized their base-rate results within the context of a causality heuristic.

Actions versus occurrences. After Kruglanski (1975), Zuckerman (1978b) distinguished between behaviors that are under the actor's voluntary control (actions) and those that are not completely voluntary (occurrences). Although occurrences may be attributed to either internal or external factors, actions are by definition caused by internal factors and should not logically be affected by consensus. The reasoning is as follows: Consensus provides information about the provocation or eliciting power of a stimulus (see Anderson, 1974; McArthur, 1976; also see McArthur's, 1972, distinction between manifest and subjective verb categories). Yet if the stimulus is ruled out as a plausible (external) cause, consensus information becomes irrelevant.

To test this hypothesis, Zuckerman (1978b) had subjects read about one of two kinds of events—actions (e.g., "Jerry attended the Sunday meeting") and occurrences (e.g., "Mary passed the exam in history"). These statements were accompanied by high or low consensus, distinctiveness, and consistency information. Consistent with previous research (e.g., McArthur, 1972; Orvis et al., 1975), consensus accounted for the highest percentage of variance in stimulus attribution. More germane to the present discussion, consensus had a substantially larger effect on the attribution of occurrences than on actions. Apparently, the consensus–attribution link is strongest for behaviors that are not completely voluntary.

Summary

In sum, explicit consensus varies along a number of important dimensions that influence its efficacy. The following characteristics of the variable were reviewed: the strength or magnitude of the proportion, the salience of the information and the ease with which it may be applied, the perceived representativeness (and hence generalizability of the base-rate sample), and the causal relevance of the base rate. We turn now to a consideration of the dependent variables.

The Dependent Variables

Prediction

Subjects have been asked to predict the behavior of target members of the original sample, frequencies or individuals in a new population, and/or their own behavior. An important issue here concerns the response criterion by which subjects' performance is evaluated (for a comprehensive discussion of the response criterion controversy, see Borgida, 1978, and Wells & Harvey, 1978). It was noted earlier that the conclusions drawn about base rates and prediction have been based on one of two criteria. The first is the null hypothesis—do the predictions of base rate versus no base rate or high- versus low-base-rate subjects statistically differ at a conventionally acceptable level? If they do differ, one would conclude that consensus affected predictions; if no difference emerged, one would conclude that subjects "ignored" consensus. An alternative strategy is to compare subjects' predictions with those implied by a normative model—do the predictions of base-rate subjects perfectly match those implied by normative standards? If they do, one may

conclude that subjects made perfect utilization of base rates; if not, one would conclude that observers "underutilized" consensus. Kahneman and Tversky's (1973) lawyer–engineer study illustrates the distinction. Recall that their subjects predicted the occupations of individuals taken from a population of 70% or 30% engineers (lawyers). Overall, subjects' mean estimates were 55% in the high engineer condition and 50% in the low engineer condition, a result indicating that although subjects did not ignore the base rate (i.e., the difference between 50% and 55% was statistically significant), they did underutilize it (i.e., 55% compared to 70%).[2] With this distinction in mind, the available research indicates that although observers generally do not ignore consensus information (Nisbett & Borgida, 1975, is an exception), they do not make full utilization of it either (see Wells & Harvey, 1977; 1978).

In general, population predictions are affected by both implicit and explicit consensus, the latter being especially effective when observers are assured that the base-rate sample is representative (Hansen & Donoghue, 1977; Wells & Harvey, 1977) and large (Kassin, 1979), when the base rates are directly translatable into a prediction (Carroll & Siegler, 1977), and when they unfold sequentially (Manis, 1977). The prediction of individual cases is also affected, though not optimally, by base rates (Lowe & Kassin, 1977; Wells & Harvey, 1977; Zuckerman, 1978a), except when relevant personal information (i.e., actor-based expectancies) is also available (Carroll & Siegler, 1977; Kahneman & Tversky, 1973; Nisbett & Borgida, 1975; Zuckerman, 1978a). Finally, note that base rates appear to have a greater impact on observers' discrete predictions (e.g., Category A vs. Category B) than on subjective probabilities associated with these outcomes (Manis, Dovalina, Avis, & Cardoze, in press).

Causal Attribution

A number of important differences between predictions and attributions deserve mention. Whereas the prediction task requires direct translation from base rates, causal attribution demands that more complex inferences be made (Nisbett & Borgida, 1975). Also, in contrast to prediction data that may be compared to those implied by a formal model, "there is no generally agreed upon criterion for explanatory adequacy" (Fischhoff, 1976, p. 439). The null hypothesis (e.g., consensus vs. no consensus) rather than optimality thus serves as the unambiguous criterion by which to judge causal attributions. Finally, in contrast to the assessment of predictions, which is straightforward and operationally consistent across studies, there is considerable disagreement over how to operationalize attribution measures that are far less sensitive and reliable.

Nisbett and Bellows (1977), among others, have argued that people infer causality from their normative expectations. This relationship has been established, even in cases where base-rate information is also available (e.g., Hansen & Donoghue, 1977; Lowe & Kassin, 1977). On the other hand, observers use explicit consensus toward causal attribution only under certain well-defined conditions—when prior expectancies are neutralized and/or when the base rate is strong, salient, representative of the population, and causally relevant. Note also that sample base rates do not affect personal and situational attribution equally. Instead, they generally provide more information about the stimulus than they do about the person (DiVitto & McArthur, 1978; Garland et al., 1975; McArthur, 1976; Orvis et al., 1975; Zuckerman, 1978b; Zuckerman & Mann, in press; Vestewig, Note 2). The actual behavior of actors thus provides information about the power and characteristics of the focal stimulus or general situation (see

---

[2] Actually, Wells and Harvey (1978) are quick to point out that "proper utilization" in Kahneman and Tversky's (1973) study does not necessarily imply target case predictions of 70% and 30%. Their subjects had two sources of information—the personality sketches and the category base rates. From a Bayesian perspective, if an individual case description is both accurate and diagnostic, it can serve to overcome the prior odds and reduce subjects' reliance on the 70–30 probabilities. Consequently, a number of possible predictions could be acceptable within the normative model.

also the discussion by DiVitto & McArthur, 1978).

One final limitation within the domain of causal attribution is notable. That is, although consensus is informative for validating the causal categories of person versus situation, it is not necessarily of interest to observers who are evaluating alternative categories (e.g., ability versus effort, intentional versus unintentional). In short, the utility of consensus is restricted to a narrow range of deductively relevant causal categories (Kruglanski, Hamel, Maides, & Schwartz, 1978).

Trait Inference

A number of investigators have assessed subjects' inferences about the characteristics of the target actor and stimulus. Trait inference should follow from causal attribution such that actor-caused behaviors should yield more extreme and more confident trait ratings than situationally caused events would. As with causal attribution, dispositional inferences about the actor are often based on a comparison of his or her behavior with the *expected* norm (Ajzen, 1971; Lay et al., 1973; Lowe & Kassin, 1977; Ross et al., 1977). In other words, the actor's characteristics are inferred from his or her unexpected (i.e., low implicit consensus) behavior.

The effect of sample-based consensus on trait inferences has only recently received empirical attention. Nisbett and Borgida (1975) reported that inferences about actors' traits were unaffected by consensus. Wells and Harvey (1977), however, demonstrated that base rates do affect these inferences when the traits being assessed are relevant to the target behavior. Having read the bystander intervention study, their base-rate subjects rated nonhelping actors on trait dimensions, whereas their no-base-rate subjects evaluated the relatedness between the target behavior and each dimension. Of nine traits seen as unrelated to the target behavior, none was affected by the base rates. Yet, three out of four "relevant" traits were influenced by the consensus manipulation. Similarly, Hansen and Stonner (1978) found that consensus affects inferences about stimulus characteristics (e.g., task difficulty), but only when the base rates and attributes are perceived to be causally related.

Summary and Conclusions

The present review suggests that any conclusions concerning the effects of consensus must be qualified—by delineating what type of consensus, what type of effect, and compared to what response criterion. Normative expectancies that are based on self-observation (i.e., the false-consensus effect) or previous other-observation (i.e., Jones & McGillis's, 1976, consensus variable) provide an initial basis for prediction and a frame of reference within which causes are inferred. These expectancies may be of a general nature or they may be refined by a perceiver's knowledge about the (class of) target actor and surrounding behavioral situation. Explicit, sample-based consensus (i.e., Kelley's, 1967, conception of a covariation across actors) is similarly employed, but under somewhat restrictive circumstances. That is, base rates appear to be relatively ineffective when they are either too inconsistent or are redundant with normative expectations. In some studies, the power of consensus has thus been demonstrated only when actor- or situation-based expectancies have been neutralized. In other studies, consensus utilization has been increased by varying characteristics of the experimental manipulation such as the magnitude of the consensus proportion, the salience of the base rate (sequential vs. simultaneous presentation, order of information presentation) and the ease with which it may be applied (translatability), the perceived representativeness of the base-rate sample (knowledge of random selection, sample size), and the causal relevance of the base rate (base rates with an explanation, actions vs. occurrences).

On the dependent variable side, consensus information is employed differently toward the various tasks of prediction, causal attribution, and trait inference. Generally stated, observers appear to underutilize but not to ignore base rates when making categorical and behavioral predictions. This conclusion is tempered, of course, by the host of factors that strengthen the presentation of base rates.

For making causal attribution and trait inferences, consensus seems to have a greater impact on stimulus than on person inferences. Finally, only traits and characteristics perceived as relevant to the target behavior are influenced by consensus information.

To date, a wide variety of issues surrounding the consensus controversy have been addressed. These include actor–observer differences in base-rate utilization, developmental trends in the use of consensus, the relative efficacy of consensus and distinctiveness, concrete versus abstract information, response criteria in social judgment research, and so on. What has emerged from this recent surge in research is an empirical, though somewhat atheoretical, redefinition of the boundary conditions for a consensus effect. Yet two important issues remain largely unresolved. First, how do normative expectancies develop and on what informational characteristics are they based? The literature suggests that implicit consensus is a viable determinant of observers' causal beliefs. Nevertheless, a theoretical account of these expectancies, one that would enable us to predict their direction and magnitude, is currently lacking. A second important issue demanding theoretical integration concerns the relationship between implicit and explicit consensus. In most life situations, people observe base rates for events that are high or low in their subjective probabilities of occurrence. Although the available data indicate that base rates are more effective when information about the target actor or situation is absent, nobody has tested the logical hypothesis that the degree of discrepancy between implicit and explicit consensus mediates utilization of the latter. At this point, attention might fruitfully be directed toward examining this relationship.

Learned Helplessness and Learned Effectiveness: Effects of Explicit Response Cues on Individuals Differing in Personal Control Expectancies

W. Larry Gregory, George M. Chartier, and Mark H. Wright
Arizona State University

Female undergraduates ($n = 62$) who scored as extreme internals or externals on the Mirels Personal Fate Control Scale participated in a partial replication of Hiroto's learned helplessness experiment. Lights were added to the treatment apparatus, which made explicit to subjects the contingency or noncontingency between their responses and the termination of an aversive tone. As predicted, the performance of internals was significantly impaired by uncontrollability (learned helplessness), while that of externals was facilitated by controllability (learned effectiveness). Externals performed as well as internals in the "escapable" condition, but their performance was inferior to that of internals in the control condition. Following "inescapable" treatment, internals performed worse than externals. These results are supportive of Lefcourt's theory of cue explication. Implications for locus of control and learned helplessness research are discussed.

The behavioral consequences of both the experimental induction of learned helplessness (Abramson, Seligman, & Teasdale, 1978; Maier & Seligman, 1976) and pre-extant, generalized perceptions of externality (Lefcourt, 1976; Phares, 1976) have been examined in a study by Hiroto (1974). Hiroto used an instrumental learned helplessness induction procedure that has since become common: Subjects, told there is something they can do to terminate an aversive tone, are seated before a small box on which there is a button. In the "escapable" treatment condition, pressing the button terminates the tone. In the "inescapable" condition, nothing the subject does terminates the tone. Rather, it is terminated automatically. Hiroto concluded that the effects of inescapable treatment parallel those of pre-extant externality: Subjects treated with inescapable noise performed significantly more poorly on a subsequent soluble task than did subjects not treated with inescapable noise; and the performance of external locus of control subjects was inferior to that of internal locus of control subjects across all experimental conditions.

Although it is typically found that internals outperform externals at tasks when instructions emphasizing skill are used (Lefcourt, Lewis, & Silverman, 1968; Rotter & Mulry, 1965; Watson & Baumal, 1967), Hiroto's (1974) results indicating that the performance of internals was superior to that of externals in the inescapable condition are puzzling when juxtaposed with other locus of control studies. These studies have shown that internals adjust their aspirations downward following failure, whereas externals are likely to display atypical aspiration shifts (Feather, 1968; Lefcourt, 1967; Lefcourt & Ladwig,

1965), that internals indicate that they have no control over a situation after failing to avoid an aversive outcome (Gregory, 1978), that internals perform worse than externals on a digits-backwards task when they expect to receive uncontrollable shocks (Houston, 1972), and that internals perform worse than externals on an anagram task following failure (Garrett & Willoughby, 1972). It would seem, then, that internals are often more adversely affected by negative experience than are externals, although Hiroto's findings suggest the opposite.

One possible explanation for these apparently discrepant results might lie in a seemingly minor procedural element: Hiroto (1974) did not utilize lights or other adjunctive feedback stimuli on the treatment apparatus to make explicit to the subjects the contingency or noncontingency between the subjects' button-pushing responses and the termination of the aversive tone. The use of these lights has since become standard during the treatment phase of learned helplessness experiments when instrumental learning is involved (Hiroto & Seligman, 1975; Miller & Seligman, 1975; Price, Tryon, & Raps, 1978; Sacco & Hokanson, 1978). Hence, during the inescapable treatment, it may be argued that some of the subjects pushed the response button just prior to or simultaneously with the automatic termination of the tone. Since there were no response contingency lights to inform a subject as to whether he or she had terminated the tone or whether it had gone off automatically, some subjects might have perceived a relationship between their response and the termination of the tone. Having experienced partial reinforcement, these subjects would be more likely to persist during the second phase of the experiment. Since Hiroto found that internals made significantly more responses than externals did during the inescapable treatment (*Mdn*s = 21 and 5.5, respectively), this scenario is more likely to have occurred for the internal subject than for the external subject. A test of this explanation would require only a partial replication of the Hiroto procedure with the addition of response contingency lights to the treatment apparatus. If this explanation is valid, then Hiroto's finding should be reversed: For subjects in the inescapable condition, the performance of internals should be inferior to that of externals.

But what effect should the addition of the response contingency lights have on the behavior of internals and externals in the control and escapable conditions? The performance of control condition subjects should be unaffected, since there is no treatment and the response contingency lights are inapplicable. Thus internals should again outperform externals, as in Hiroto's (1974) study.

Different predictions can be made for the escapable condition. A number of studies have shown that explicit task cues have a positive effect on the behavior of externals (Dollinger & Taub, 1977; Gregory & Nelson, 1978; Lefcourt, 1967; Lefcourt & Wine, 1969; Taub & Dollinger, 1975). These studies have demonstrated that providing reward or purpose for a task raises the motivational level of externals to equal that of internals or results in externals making aspiration shifts more typical of internals following a success or a failure. Lefcourt (1967) has labeled this process "cue explication" and has restricted its meaning to making the external subject "aware of the availability of reinforcements, and perhaps, of the methods for maximizing his chances of succeeding in given tasks" (p. 378).[1] In a learned helplessness experiment, a response contingency light would make ex-

[1] One study (Wolk & DuCette, 1974, Study 2) involving cue explication has failed to find that it alters the performance of externals to equal that of internals. Under high cue explication conditions, Wolk and DuCette found that externals failed to display intentional or incidental learning at a level equal to that of internals. But it is questionable whether the high cue explication manipulation met the conditions prescribed by Lefcourt, since it consisted of informing subjects that they would be tested on some aspect of the task in addition to taking a test already specified. This does not make explicit the reinforcements available for a good task performance. This procedure could have produced debilitating anxiety or test anxiety, which are associated with externality (Feather, 1967; Ray & Katahn, 1968; Watson & Baumal, 1967). Supporting this argument, Wolk and DuCette found that high cue explication externals performed worse than low cue explication externals in their high difficulty condition.

plicit to the external subject that he or she had just been reinforced for a correct task performance. Whereas Hiroto (1974) found internals to exhibit superior performance in the escapable condition, the cue explication literature would suggest that the addition of the response contingency lights in the escapable treatment condition would enhance the performance of externals to equal that of internals.

Predictions

It was predicted that the addition of response contingency lights to the treatment apparatus for an instrumental learned helplessness induction procedure would result in (a) no differences in performance between internals and externals in the escapable condition, (b) internals outperforming externals in the control condition, and (c) externals outperforming internals in the inescapable condition. For external subjects only, the theory of cue explication predicts that (d) the performance of subjects in the escapable condition should be enhanced above that of subjects in the control condition. Comparative performance among internals would be unaffected by explicit response cues, and they should display the typical learned helplessness pattern: (e) Inescapable treatment should produce performance decrements when compared to the control condition, whereas (f) the control condition should not differ from the escapable treatment condition.

Method

At Arizona State University, students enrolled in introductory psychology must write three brief research reports or participate in 3 hours of laboratory research. Students participating in this experiment had chosen the latter option.

Subjects were 62 females who scored at the extremes (0–2 or 7–9) of the Mirels (1970) personal fate control scale. This was a subsample of 183 females to whom the Rotter (1966) Internal–External Locus of Control Scale was administered immediately prior to the experiment. Subjects were assigned randomly to either the escapable treatment, control, or inescapable treatment conditions. The relatively greater frequency of internals and the method of immediate assignment to condition resulted in unequal numbers of subjects per cell of the 2 × 3 factorial design. Although Hiroto (1974) used subjects scoring at the extremes of the DeKalb Survey Tests (Student Opinion Survey, Form I-E, 1; see James, Note 1), the Mirels scale was employed here, since it is assumed to be more predictive of control over personal events and it is derived from the more commonly used Rotter I-E scale. The James and Rotter scales are highly similar in content. Only female subjects were used, due to their availability in the subject pool.

Apparatus

The treatment apparatus, adapted from Hiroto and Seligman (1975), consisted of a spring-loaded button housed in the center of a circular disc, 30.5 cm in diameter and 7.6 cm high, with two circular lights, one red and one green, each 1.3 cm in diameter, located on either side of the button. In the escapable condition two button presses terminated the aversive tone and stopped a remote timer. In the inescapable condition the button was electronically rendered inoperative.

The test phase apparatus was a modification of Turner and Solomon's (1962) human shuttle box. By sliding a knob to either extreme end contact could be made with a hidden microswitch that controlled tone termination. Specifications of the manipulandum are included in Hiroto (1974).

The aversive stimulus was a 3000 Hz tone generated by a Hewlett Packard audio oscillator, presented to the subject through Realistic Nova 10 stereo headphones at 100 db. Formal instructions were presented to the subject on typewritten index cards. All response latencies were measured by a standard (1/100 sec) automatic timer, and intertrial intervals (ITI) were timed manually on a stopwatch. The oscillator, timer, and controlling circuitry were located in an adjacent room separated by a one-way mirror.

Procedure

Treatment. Following administration of the I-E scale, each subject was escorted individually to the experimental room and was informed that the experiment concerned the effects of noise pollution on the performance of simple tasks and that the subject's continued participation in the study beyond a brief sample of the unpleasant but harmless tone was optional. If, after a 3 sec sample of the 3000 Hz tone, the subject agreed to continue, the appropriate treatment phase was begun. Three subjects refused to participate (one internal and two moderates).

Subjects in the escapable and inescapable conditions were seated at a table on which the treatment apparatus was located. The experimenter uncovered the apparatus and presented instructions to the subject concerning the noise, that there was something she could do to stop it, and the function of the two lights. These instructions were identical to those of Hiroto and Seligman (1975), with the addition of a statement reiterating the function of the two lights: "*You* will have successfully stopped the noise *only* when the green light comes on."

Forty unsignaled trials with an ITI range of 15 to 25 sec and a mean of 17.4 sec followed. In the escapable treatment, pressing the button twice within 5 sec after tone onset terminated the tone, and the green light flashed on briefly. Response latencies were recorded. If the correct response did not occur within 5 sec of tone onset, the tone terminated automatically, the red light flashed, and a response latency of 5 sec was recorded.

In the inescapable treatment condition, exposure to tone duration and pattern was yoked to the subject's counterpart in the escapable condition and was independent of the button. The tone was not escapable, and the red light flashed at the termination of each trial.

Control subjects were not exposed to the treatment apparatus but worked on a questionnaire composed of 100 items selected from the California Psychological Inventory on the basis of relatively neutral content, during which they received yoked exposure to the series of 40 tones. Subjects in this condition received instructions on completing the inventory and were told, "From time to time while you are filling out the questionnaire a noise will come on. Please continue working on the questionnaire."[2]

Test task. Immediately after treatment, subjects in all three groups were seated at a table on which the covered test task apparatus was located and were given instructions concerning it identical to those of Hiroto and Seligman (1975). These instructions were similar to those for the first task, but with no references to lights, since they were not present on the test apparatus.

The test phase consisted of 20 signaled 10 sec escape–avoidance trials. A 5 sec amber light, located at the midpoint of the shuttlebox cover, preceded the 3000 Hz, 100 db tone, with the light's termination coinciding with the onset of the tone. The ITI ranged from 10 to 25 sec, with a mean of 15 sec.

Prior to the first trial the sliding knob was always located at the midpoint of the channel. The appropriate response was moving the knob to one side of the shuttlebox on one trial, moving it to the opposite side on the next, and alternating for the remaining trials. Although the subject was informed only of the possibility of escape, tone avoidance was possible by making the appropriate response after the onset of the warning light and before the onset of the tone. A successful avoidance response (i.e., a response latency of less than 5 sec.) terminated the warning light and prevented exposure to the tone. A successful escape response (i.e., a response latency between 5 and 10 sec) terminated the tone. If the subject failed to avoid or to escape, the tone was terminated automatically and a response latency of 10 sec was recorded.

Dependent Measures

Five test task-dependent measures were used to assess performance. These were: (a) the "conditional probability" of an escape or avoidance response, defined as the percentage of times a successful response (escape or avoidance) was preceded by a successful response; (b) the number of failures to avoid or escape, defined as the number of responses with latencies of 10 sec; (c) success criterion, defined as the number of trials needed to reach either an avoidance or an escape criterion of three consecutive escape or avoidance responses (subjects who failed to reach either were assigned scores of 21); (d) the mean overall response latency for the 20 trials; and (e) the number of trials needed to reach an avoidance criterion of three consecutive avoidance responses. Although partially redundant with (c), (e) was included as an exploratory measure to determine if any differences existed between internals and externals in their acquisition of avoidance responses. Latency was included as a dependent variable, since previous studies have utilized it, although Buchwald, Coyne, and Cole (1978) argue that it may be a poor measure of motivation in a learned helplessness experiment. At least two learned helplessness studies (Douglas & Anisman, 1975; Tennen & Eller, 1977) have failed to find significant main effects for this variable. The other three dependent variables have all been used previously in learned helplessness research. The conditional probability measure is assumed to assess cognitive learning ability, whereas the others index motivational processes (Klein & Seligman, 1976).

Additionally, six questionnaire measures were included at the end of the experiment; these required the subject to rate her treatment experiences on 7-point bipolar scales. These were: (a) her motivation to solve the problem; (b) the extent to which she felt in control of her success and failure; (c) the level of her frustration; (d) the level of her irritation; (e) the level of her depression; and (f) the aversiveness of the tone. The second of these measures was intended as a manipulation check; the others were included as crude exploratory measures of possible differences in subjective state.

Results

Self-Report Measures

A 2 (Internal vs. External Personal Control Orientation) × 3 (Escapable, Control, or Inescapable Treatment Condition) analysis of variance (ANOVA) was performed on each of the self-report measures. Only one significant

[2] At least two other studies (Gatchell & Proctor, 1976; Hiroto & Seligman, 1975) have employed a control group that was told that noise was inevitable. Neither study found interference effects in the control group subjects. Apparently, informing subjects not to try to do anything about the noise precludes formation of perceptions of helplessness (Buchwald, Coyne, & Cole, 1978, p. 184).

effect was revealed. A main effect for treatment was found for subjects' perceptions of control, $F(2, 56) = 3.55$, $p < .035$. Simple effects analysis revealed that subjects in the inescapable condition perceived less personal control than did control condition subjects, $F(1, 56) = 6.23$, $p < .016$, whereas control condition subjects did not differ from escapable condition subjects, $F(1, 56) < 1$, *ns*. This suggests that the experimental manipulation of perceived control over events was successful.

Random Assignment of Subjects

To insure that the assignment of subjects to conditions had been random, the same 2 × 3 ANOVA was performed on subjects' personal control scores. Neither the interaction nor the main effect for treatment condition were significant, both Fs < 1. A main effect for personal control orientation was found, $F(1, 56) = 1248.18$, $p < .001$, indicating that subjects in the internal conditions were significantly more internal than subjects in the external conditions.

Multivariate Clustering

Since the conditional probability measure was assumed to assess cognitive learning ability, it was analyzed apart from the other dependent variables, which were assumed to assess motivation. Also, since the avoidance criterion variable was included as an exploratory measure, and because the use of response latencies has been questioned previously, these variables, along with the number of failures to escape or avoid and the success criterion variables, were subjected to a test of the assumption of homogeneity of the variance–covariance matrices (Bock, 1975, p. 412). This was done in order to determine the appropriateness of analyzing these variables as a single multivariate vector. This test indicated that the four variables together violated the assumption, $\chi_c^2(50) = 104.83$, $p < .001$. Accordingly, a principal components analysis with iterations utilizing the varimax rotation procedure (Nie, Hull, Jenkins, Steinbrenner, & Bent, 1975) was undertaken to determine an appropriate clustering of the four variables. The principal components analysis resulted in two unrotated factors with eigenvalues greater than 1. The remaining two unrotated factors had eigenvalues of .15 or less and accounted for less than 5% of the variance. The first rotated factor accounted for 72.5% of the variance and consisted of the number of failures to avoid or escape and the success criterion variables. The second rotated factor accounted for 27.5% of the variance and consisted of the avoidance criterion and response latency variables. Thus, it was determined that separate multivariate analyses of variance would be performed on the variables represented by these two factors. All subsequent analyses utilized the MANOVA program (Clyde, 1969), and planned comparisons were employed as justified by the specific predictions of the study (Hays, 1973, p. 582; Winer, 1971, pp. 175, 384). The MANOVA program uses least squares analyses when performing univariate analyses of variance.

Performance of Internal Versus External Subjects

Planned comparisons were used to contrast internals to externals in each of the three treatment conditions. The planned comparison F value for each dependent variable is displayed in Table 1. The means for all cells on the performance measures are displayed in Table 2. Figure 1 displays graphically the results of the conditional probability measure, typical of the overall pattern of responses.

Escapable condition. As can be seen from Table 2, there were no significant differences between internals and externals on any of the performance measures in the escapable condition. This supports the prediction that externals perform as well as internals when given explicit response cues.

Control condition. As predicted, when there was no prior experience with explicit response cues, as in the control condition, internals outperformed externals on the conditional probability, number of failures, and

Table 1
Planned Comparison F *Values for the Multivariate and Univariate Contrasts*

Planned comparison and condition	Multivariate contrast *F*		Univariate contrast *F*				
	NF & SC	RL & AC	CP	NF	SC	RL	AC
Internal vs. external subjects							
Escapable	<1	<1	<1	<1	<1	<1.05	<1.15
Control	2.51*	1.53	5.04**	4.27**	4.81**	3.02*	1.82
Inescapable	2.58*	<1	4.10**	4.98**	2.08	<1	<1
Internal subjects							
Escapable vs. control	<1	7.04***	<1	1.13	<1	2.41	9.53***
Inescapable vs. control	10.05***	4.43**	19.28***	20.35***	11.26***	8.57***	4.77**
External subjects							
Escapable vs. control	2.39*	3.44**	5.05**	4.74**	4.48**	1.45	<1
Inescapable vs. control	<1	<1	<1	<1	<1	<1	<1

Note. The degrees of freedom for all multivariate contrasts are 2 and 55, whereas they are 1 and 56 for all univariate contrasts. CP = conditional probability measure. NF = number of failures to escape or avoid measure. SC = success criterion measure. RL = response latency measure. AC = avoidance criterion measure.
* $p < .10$. ** $p < .05$. *** $p < .01$.

success criterion measures.[3] No significant differences were obtained for the response latency and avoidance criterion measures, although the means were in the predicted direction.

Inescapable condition. As predicted for the inescapable condition, where there were explicit cues indicating that subjects failed to control the outcome, internals performed significantly worse than externals did on the conditional probability and number of failures measures. Differences on the other measures were in the predicted direction but were nonsignificant.

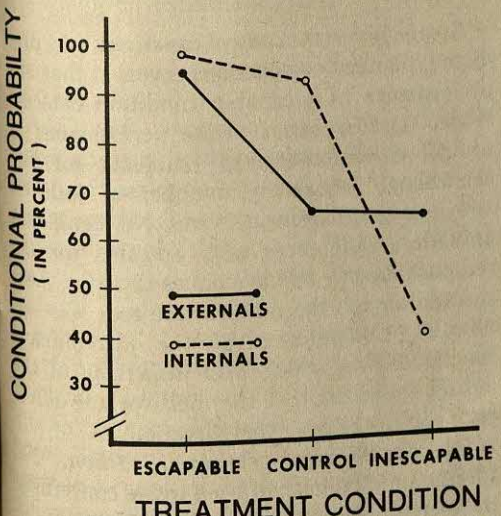

Figure 1. Conditional probability by treatment condition.

Performance of Internals Across Treatment Conditions

Escapable versus control condition. It was also predicted that planned comparisons would not reveal significant differences between escapable condition–internal subjects and control condition–internal subjects. With the exception of the avoidance criterion measure, no significant effects were obtained. The multivariate comparison for the combined avoidance criterion and response latency mea-

[3] Healy (1969) has noted that since univariate confidence intervals are located along a linear axis, whereas bivariate confidence intervals are elliptical, it is possible to reject both univariate null hypotheses while failing to reject the bivariate null hypothesis. This is known as Rao's paradox, and Baron (1978) has published results on its occurrence for a trivariate case.

Table 2
Means for Each Performance Measure

Measure	Treatment condition: Escapable *M*	Control *M*	Inescapable *M*
Internal orientation			
Conditional probability	97.8	93.0	39.1
Number of failures	0.3	1.3	11.0
Success criterion	3.4	4.2	12.0
Response latency	5.9	4.5	7.2
Avoidance criterion	19.4	12.3	17.4
External orientation			
Conditional probability	94.6	65.4	63.8
Number of failures	0.8	5.7	6.2
Success criterion	4.0	9.3	8.7
Response latency	5.0	6.2	6.4
Avoidance criterion	16.6	16.1	16.7

Note. With the exception of the conditional probability measure, low numbers represent better performance. In the internal personal control orientation, escapable $n = 17$, control $n = 12$, and inescapable $n = 9$. In the external personal control orientation, escapable $n = 8$, control $n = 7$, and inescapable $n = 9$.

sures was significant, and inspection of the means indicates that internals in the control condition, contrary to prediction, were superior in performance to the internals in the escapable condition. A brief comment may be in order concerning this unexpected finding. For the other measures of cognitive learning and motivation, explicit response cues indicating that internals were successful in escaping the aversive stimuli did not serve to enhance their subsequent test task performance above that of control condition–internal subjects. However, the explicit cues may have led internals to overlearn an escape response to the extent that avoidance learning on the subsequent task was debilitated. This may occur only under conditions of explicit response cues, but further research is indicated on this topic. Given success, internals may be prone to stereotypic responses and fail to explore the possibilities of even more beneficial behaviors.

Inescapable versus control condition. As predicted, planned comparisons revealed that the performance of inescapable condition–internal subjects was significantly worse than that of control condition–internal subjects for all measures.

Summary of response pattern for internal subjects. Overall, internals displayed the predicted learned helplessness pattern. That is, the performance of internal subjects in the inescapable condition was inferior to that of internals in the control condition. With the exception of the avoidance criterion measure, the performance of internal subjects in the escapable condition was not different from that of internals in the control condition. For the avoidance criterion measure, control condition–internal subjects outperformed escapable condition–internal subjects.

It appears that an explicit response cue indicating that they are escaping an aversive stimulus does not serve to enhance the performance of internal subjects above that of control condition–internal subjects, although it can serve to interfere with subsequent avoidance learning. By contrast, an explicit response cue indicating that they are failing to escape an aversive stimulus does serve to debilitate the performance of internals in comparison to that of control condition–internal subjects.

Performance of Externals Across Treatment Conditions

Escapable versus control condition. As predicted, planned comparisons revealed that the performance of escapable condition–external subjects was superior to the performance of control condition–external subjects for the conditional probability, number of failures, and success criterion measures. No significant univariate differences were revealed for the response latency and avoidance criterion measures, although the multivariate root was significant. Computation of the discriminant function scores, along with inspection of the means, indicated that the multivariate difference was in the predicted direction.

Inescapable versus control condition. No specific predictions had been made concerning the performance of external subjects in the inescapable condition relative to the performance of external subjects in the control con-

dition. To remain consistent with the previous analyses, however, planned comparisons between these groups were conducted. No significant differences were obtained on any of the performance measures. Since planned comparisons are an extremely powerful technique for detecting differences, should they exist, the failure to obtain any significant differences for any of the univariate or multivariate contrasts should underscore the apparent lack of differences between the performances of external subjects in the inescapable and control conditions.

Summary of response pattern for external subjects. It appears that externals did not display learned helplessness, since there were no differences between the control condition and the inescapable condition for any of the dependent measures. As predicted, the performance of externals in the escapable condition was superior to that of externals in the control condition for most of the performance measures. It would appear that an explicit response cue indicating that they are escaping an aversive stimulus does serve to enhance the subsequent performance of external subjects above that of control condition–external subjects. By contrast, an explicit cue indicating that they are failing to escape an aversive stimulus does not serve to debilitate the performance of externals in comparison to control condition–external subjects.

Discussion

Additional conclusions regarding cue explication and the performances of internals and externals would be possible, had the present design included nonexplicated escapable and inescapable conditions, as in Hiroto's (1974) study. Nonetheless, the cue explication hypothesis (Lefcourt, 1967) received substantive support. Following escapable treatment on an apparatus equipped with response cue lights, the performance of externals was significantly enhanced above that of control condition–external subjects. Additionally, these escapable condition–external subjects equalled in performance the escapable condition–internal subjects. It appears that making explicit to the external subject the contingency between response and outcome is one means of cue explication. The finding that inescapable condition–internal subjects performed worse than both control condition–internal subjects and inescapable condition–external subjects when explicit response cues were provided suggests that cue explication may have a negative counterpart for internal subjects. When internals are made aware of the lack of availability of reinforcements, or the lack of contingency between behavior and outcome, their subsequent performance is debilitated to a level inferior to that of externals. This point suggests a potential for behavioral problems in persons with extremely internal control orientations.

Previous researchers (DuCette & Wolk, 1973) have argued that internals are cognitively superior to externals because they take fewer trials to criterion on a skill task. In the present study, internals and externals in the escapable condition did not differ in their subsequent acquisition of the escape-avoidance behavior. Thus, the provision of explicit cue responses can result in externals equalling internals in learning ability. It is important to note that this effect was obtained on a subsequent (albeit highly similar) task that did not utilize explicit cues. This indicates that the motivational and cognitive effects of cue explication during the treatment phase generalized to the second task. Unlike much of the locus of control research that attempts to delineate differences between internals and externals, this study seems to refocus attention on the neglected issue of alleviating or altering the behavioral consequences of an external perception of control. The present results are even more dramatic, considering that they were obtained from individuals with extreme external control orientations. Whether our findings are generalizable to extreme males as well as females is of course an empirical question, although the lack of consistent sex differences in the internal–external literature would suggest such applicability.

The present results also lead us to consider some possible antecedents and consequences of an external expectancy for control. Given that the performance of externals in the control condition was inferior to that of externals

in the escapable condition, it may be argued, as did Hiroto (1974), that one consequence of an external orientation is some degree of pre-extant helplessness for skill tasks. Since externals appeared to be helpless prior to entering the experimental situation, their altered performance in the escapable condition might best be termed "learned effectiveness." Further, since there were no differences in performance between control condition–externals and inescapable condition–externals, it is clear that the pre-extant helplessness of externals in the inescapable condition was not increased by the treatment. Since helplessness is produced (in instrumental induction studies) by failure to control an aversive experience, we propose that one developmental antecedent of externality is repeated failure to control aversive experiences. However, this speculation on externality is qualified by Gregory's (1978) findings that the Rotter (1966) I–E scale and the Mirels (1970) personal fate control scale are predictive only of control over negative outcomes or aversive events. Externality for nonaversive events or positive outcomes would, of course, be expected to follow from different antecedents.

Locus of Control, Cue Explication, and Learned Effectiveness

The present findings suggest a reinterpretation of another study involving locus of control and learned helplessness. Following a pretreatment consisting of contingent or noncontingent feedback on a concept formation task represented as a test of "spatial reasoning ability," Cohen, Rothbart, and Phillips (1976) found what they interpreted as learned helplessness for external subjects on both a Stroop color task and a maze tracing task. A performance decrement for internal subjects was found only on the maze tracing task. In the contingent condition, subjects received accurate feedback concerning the correctness of their choice after each concept formation slide. Cue explication theory would predict that external subjects would perform as well in this condition as internal subjects, as indeed was found. Although the performance of external subjects in the contingent condition was superior to that of external subjects in the noncontingent condition, one cannot determine whether learned helplessness or learned effectiveness occurred. As Buchwald, Coyne, and Cole (1978) note, in the absence of a control condition it is impossible to know whether performance enhancement (or learned effectiveness, as we have termed it) or interference has occurred. Given the procedure employed by Cohen et al. in the contingent condition, it is possible that their external subjects displayed learned effectiveness and, as in the present study, their internal subjects displayed learned helplessness. The finding that internal subjects displayed performance decrements on only the maze tracing task may have been due to its greater similarity to the training task.

Finally, it should be noted that one unpublished study (Benson & Kennelly, Note 2) has found results identical to the present study. Benson and Kennelly treated male and female subjects who had scored at the extremes of Levenson's (1974) locus of control scale with explicit contingent or noncontingent feedback on a concept formation task. Using anagram problems as the test task, they found that relative to control condition subjects, "the performance of internals was impaired by pretreatment with insoluble problems. The performance of externals was not impaired by pretreatment with insoluble problems, but facilitated by pretreatment with soluble problems (p. 7)." Combined, the results of Cohen et al. (1976) and Benson and Kennelly extend and generalize the notion that cue explication can improve significantly the performance of externals.

Conclusions

The present study has implications for research in two areas. The examination of learned helplessness might include systematic investigation of the effects that seemingly minor procedural variations have on the behaviors of subjects with individual differences, such as locus of control. Locus of control research could benefit by studying the effects of explicit cues on the behavior of internal and external locus of control subjects, and from

refocusing some attention on this inadequately researched area.

New JPSP Format Delayed Until April

Recent issues of this journal carried an announcement that the *Journal of Personality and Social Psychology* would appear in January 1980 under new policies and in a new sectioned format. However, in order to publish the backlog of manuscripts accepted under present policies, the first three issues of 1980 will continue to carry articles accepted under Clyde Hendrick's Acting Editorship.

This journal will appear in April as a sectioned journal edited by Melvin Manis, Ivan D. Steiner, and Robert Hogan, as previously announced.

An Empirical Analysis of the Correlations Between Leadership Status and Participation Rates Reported in the Literature

R. Timothy Stein and Tamar Heller
University of Illinois at Chicago Circle

Many studies of small group leadership have reported a positive relationship between leadership status and the rate of verbal participation. The leadership participation relationship has been attributed to (a) the performance of task leadership behaviors, (b) task skill and knowledge, (c) social status characteristics, and (d) the presence of observers. Hypotheses based on these four explanations were generated and tested using 72 correlations reported in the literature as data points. The relationship of a large number of situational variables to the leadership–participation rate relationship was also examined. In a multiple regression analysis, four variables accounted for 63% of the variance in the leadership–participation rate correlations. The first three explanations were supported. They can be integrated if the moderating effect of task competence and social status on the performance of task leadership behavior is recognized.

A positive relationship between verbal participation rates and leadership status is frequently reported in the small group literature. In reviewing that literature, the authors uncovered 77 correlations between the variables. The mean was .65, and the range was from −.48 (Gustafson & Harrell, 1970) to .98 (Bates, 1952); only 4 were negative. In these studies new groups were formed for the research or for classroom activities. Either observers or the group members rated the participants on leadership. These ratings were measures of leadership status because all the group members, and not just those who emerged to a leadership position, were included. Measures of the relative amounts of talking by the group members were obtained from audiotapes or from observers' records (e.g., the number of words spoken).

Other lab studies have shown a covariation between participation and leadership status. Several authors report higher mean leadership ratings for high participants (e.g., Carter, Haythorn, Shriver, & Lanzetta, 1950; Gintner & Lindskold, 1975). Also, experimenters have manipulated the relative amounts of talking by group members. Parallel shifts in peer judgments about the participants' leadership followed (e.g., Bavelas, Hastorf, Gross, & Kite, 1965; Zdep & Oakes, 1967).

The covariation of leadership status and participation rates has been attributed to (a) the performance of task roles, (b) task skill and knowledge, (c) social status characteristics, (d) the presence of observers, and (e) motivation. Although an extensive literature points to a relationship between leadership and participation, the research described here is the first to compare the explanations to determine how well they account for the rela-

The authors thank Steven Cooley for rating the tasks and the leadership functions, Herbert Stenson for his advice on the statistical analyses, Carolyn Clark for secretarial support, Joyce Rozwadowski for her assistance with literary revisions, and Mary Glenn Wiley and L. Richard Hoffman for their comments on a draft of the paper. The authors acknowledge the use of the library and computer facility at the University of Illinois at Chicago Circle and the library at DePaul University.

A summary of this research was presented to the 86th annual convention of the American Psychological Association in Toronto (Heller and Stein, 1978).

Requests for reprints should be sent to Tamar Heller, Psychology Department, University of Illinois at Chicago Circle, P.O. Box 4348, Chicago, Illinois 60680.

tionship. Hypotheses were generated from the first four explanations.[1] Additional hypotheses were formulated to include two situational parameters, group size and observer bias. Seventy-two of the correlations reported in the literature were used as data.

First, it is possible that the role performed by leaders requires their participation and wins them status. The most common division of roles in small group interaction is the distinction between task and group maintenance leadership (Hare, 1976, p. 145). Task leadership behaviors are defined as "behaviors of the individual related to his efforts to assist the group in achieving goals toward which the group is oriented" (Bales, 1958). Group maintenance leadership behaviors are "behaviors of the individual related to his efforts to establish and maintain cordial and socially satisfying relations with other group members" (Bales, 1958). The development of task leadership roles is the major thesis of emergent leadership theories (Bales, 1953; Hollander, 1958; Stein, Hoffman, Cooley, & Pearse, 1979; Stogdill, 1959). Studies that have compared leaders to nonleaders in the performance of specific behaviors have clearly indicated that leaders perform more task-related behaviors than do nonleaders (e.g., Carter et al., 1950; Kirscht, Lodahl, & Haire, 1959; Morris & Hackman, 1969). In summarizing this research, Stein and Heller (Note 1) noted that leaders were significantly more active than nonleaders in performing task leadership behaviors in 51 of 76 (67%) statistical tests.[2] The task leadership activities included problem identification, proposing solutions, seeking and giving information and opinions, and initiating structure. The performance of group maintenance activities differentiated leaders from nonleaders in only 5 of 24 tests. The following hypotheses are based on the task facilitation explanation: *Hypothesis 1a: Leadership–participation rate correlations in which task leadership measures are used are higher than those involving maintenance functions. Hypothesis 1b: The more general the task leadership measure, the higher is the correlation with participation rates.*

Several researchers have suggested that the leadership–participation rate relationship might be a reflection of technical competence (e.g., Gintner & Lindskold, 1975). Task skill has been shown to be related to emergent leadership in both field (Clifford & Cohn, 1964; Crockett, 1955) and lab studies (e.g., Heinicke & Bales, 1953; Moment & Zaleznik, 1963). Hemphill (1961) found that members of new groups who believed that they were more competent than others performed a higher number of leadership behaviors. In some studies, the quality and quantity of participation were manipulated (Gintner & Lindskold, 1975; Jaffee & Lucas, 1969; Reilly & Jaffee, 1970; Sorrentino & Boutillier, 1975). Even when confederates suggested the same solution to the assigned problem in different groups, their leadership ratings were dependent upon how much they talked. Thus, the quality of the solution could not account for the leadership–participation rate relationship. However, it is possible that both leadership status and participation rate differences occur because those who offer better solutions make more attempts to influence others. In that case, competency may be a basis for both influence and participation in tasks requiring skill. *Hypothesis 2: The value of the correlation between leadership status and participation is directly related to the skill requirements of the task.*

Third, Blau (1964) has theorized that members who impress others as being capable of providing task assistance are initially permitted more participation time. The personal characteristics that have been tied to these judgments include intelligence, personality traits, and social status (race, sex, and income). Of these variables, only sexual status

---

[1] A hypothesis was not formulated for the motivation explanation because data concerning individual differences on either motivation or the raters' perceptions of motivation were not reported with the leadership–participation rate correlations in the literature.

[2] Some researchers compared leaders to nonleaders on the proportion of their total behavior that fell within certain task behavior categories. In these tests, leaders were found to have a significantly higher proportion in only 5 of 40 (12.5%) comparisons (Stein & Heller, Note 1). These results indicate that leadership status is based on the number of task leadership acts, and not the proportion of one's behavior that is task leadership.

seems to be strongly related to both participation rates and leadership. Comparisons of sexes have shown men to be more verbose and more influential (e.g., Strodtbeck, James, & Hawkins, 1957), and more proactively involved in performing the task (e.g., Strodtbeck & Mann, 1956).

Hypothesis 3: The correlation between leadership status and participation is higher in mixed-sex than in same-sex groups.

Finally, Wilson (1971) has suggested that the leadership–participation rate relationship is an experimental artifact. Members with high assertiveness and ascendancy needs are thought to respond to the presence of an observer with high participation and ingratiating behaviors. The other members rate these people high on leadership because they assume that the observer identifies leadership with dominance, influence, and high participation rates.

Hypothesis 4: The correlation between leadership and participation is lower in groups unaware of being observed.

Hypotheses were formulated for two situational variables, group size and observer bias. Other independent variables were included for exploratory research. Several researchers have found that the differences in participation rates among group members are dependent upon group size (see Hare, 1976, pp. 219–221). After reviewing several studies, Thomas and Fink (1963) concluded that greater size was associated with an increase in organization and division of labor. These findings suggest that (*Hypothesis 5*) *the correlation between participation rates and leadership status is directly related to group size.*

Greater observer dependency on participation rates in formulating leadership judgments has been suggested in three studies (Juola, 1957; Kanungo, 1966; Stein, 1977). Observers, but not the group members, failed to differentiate between task and maintenance functions, which suggests that the observers used a more global criterion in evaluating leadership.

If the observers are so biased, then (*Hypothesis 6*) *the correlations between leadership and participation involving observer leadership ratings are higher than those based on peer ratings or self-ratings.*

Method

Dependent Measure

Seventy-two correlations (Pearson or Spearman), reported in the literature between emergent leadership status and the verbal participation rates of group members were used as data for the dependent variable (see Table 1).[3] The use of more than one correlation from a study reflects differences in tasks, group composition, the degree of group consensus on who was leader, the length of interaction covered, or the leadership or participation measures used. Three of the values (from Morris & Hackman, 1969) include both emergent and appointed leaders. No other data of this nature were found for formal leaders. The authors transformed the correlations to Fisher *z* scores for the statistical tests.

The leadership–participation rate correlations are

[3] Four correlations were excluded because of insufficient information about the task and subject population (.96, French, 1950; reported in Bass, 1954) and/or because an interaction time was used that far exceeded that of the other studies (.95 and .94, Norfleet, 1948; and .98, Bates, 1952). The .89 value reported by Stang, Castellaneta, Constantindis and Fortuno (1976) came to the authors' attention too late to be included in the analysis.

not equally stable. The *n*s for the correlations differ, and in some instances median rhos were used. However, the differences in error variance due to different sample sizes are randomly distributed; sample size was uncorrelated with the *z* transformations of the leadership–participation rate correlations ($r = -.12$, *ns*). For this reason, the values did not need to be weighted.

Independent Measures

The study included 28 independent measures related to (a) the type of task, (b) the characteristics of the task, (c) the nature of the group, and (d) the type of leadership measure. The data provided on these variables summarize the methodological and measurement choices made by past researchers. From this summary, possible limitations on the generalizability of the leadership–participation rate relationship can be identified.

Task type. All the correlations are from groups assigned a task. The tasks were categorized according to four types: (a) problem solving, deriving a group solution to a problem ($n = 16$); (b) verbal production, preparing verbal presentations or creating stories ($n = 20$); (c) opinion, discussing issues without having to reach a group decision ($n = 34$); and (d) manipulation, assemblying objects ($n = 2$).

Task characteristics. The task dimensions included the six identified by Shaw (1971, 1973) and three additional measures: (a) skill required, requirements for special training or knowledge; (b) difficulty, including time pressures, skill or knowledge required, number of operations, knowledge of the desired outcome, amount of effort needed, and the degree of the subjects' familiarity with the task; (c) goal clarity; (d) solution multiplicity, the number of possible solutions and the extent to which the adequacy of a solution could be verified; (e) cooperation requirements, requirements for integrated group action; (f) manipulation–intellectual requirements, intellectual operations versus physical operations; (g) population familiarity, the occurrence of the task in the larger society; (h) intrinsic interest, interest created by the nature of the task; and (i) external motivation, consequences of performance (e.g., money, grades, the judgment of esteemed others). Eight-point rating scales were used (after Shaw, 1973). Higher scale values indicate a higher level of the dimension in question (e.g., a more difficult task).

Nature of groups. In order to identify different types of groups, five dichotomous variables were set up. For the first, a score of 1 was assigned if all the group members were males, and 0 for groups of other compositions. In a similar fashion, variables were defined for all female members, members of both sexes, college students, and group members who were aware that they were being observed. Two additional variables were the number of group members, and the group members' knowledge of one another prior to the meeting. A 3-point scale was used for the last variable.

Leadership measures. The characteristics of the leadership measures were assessed with eight variables. One variable indicated (a) whether the measure was of task leadership or maintenance leadership.[4] Other dichotomous variables indicated whether or not the leadership ratings were made by (b) peers or (c) observers, or (d) if they were self-ratings. Two time measures were used: (e) the number of minutes the group had met before the first leadership measure was taken and (f) the number of minutes before the last leadership measure. (g) Whether or not the leadership rating was meaningful to the group members, that is, if the selected leader actually functioned in any capacity, was noted. (h) Finally, the breadth of the leadership measure (i.e., how many different types of behavior it included) was rated on an 8-point scale.

Interrater Reliabilities

Two judges (including the first author) rated the leadership functions and descriptions of the task without knowledge of the correlations between participation and leadership. The Pearson correlations between the judges' ratings ranged from .79 to .97 (see Table 2).

Results

The relationships between the dependent and independent variables are presented in Tables 2 and 3. If a rating scale was used for an independent variable, the scores were correlated with the Fisher *z* transformations of the leadership–participation correlations (see Table 2). If a variable was dichotomous, *t* tests were used. The means are given in Table 3. The correlations that were assigned a score of 1, because the condition indicated by the variable name was fulfilled (e.g., correlations from groups of all males), are called "included cases." The correlations for which the condition was not fulfilled (e.g., correlations from groups other than all male) are labeled as "excluded cases."

---

[4] Some experiments used vague measures, such as "Who was the real leader of the group?" (Morris & Hackman, 1969). However, those authors and others (e.g., Bales, 1953) have shown that subjects name task leaders when asked in a general way to identify their leaders. For this reason, the general leadership measures were included with the task leadership measures. The data provide support for this decision. The mean of the 13 leadership–participation rate correlations in which general leadership measures were used was .74. It was not significantly different from the mean of .67 for correlations involving specific measures of task leadership.

Table 2
Situational Factors: Interrater Reliabilities and Correlations With the Degree of Association Between Participation Rates and Leadership

Variable	Interrater reliability[a]	Correlation

Breadth of leadership measure	.95	.13	.36**

[a] All interrater reliabilities are significant at the .001 level, $df = 20$. [b] $df = 70$. [c] $df = 55$.
* $p < .05$. ** $p < .01$.

Because the first hypothesis stated that the leadership–participation rate relationship was limited to measures of task leadership, all of the analyses were performed on both the total sample of 72 correlations and on a subsample of all the correlations that involved task leadership measures.

Tests of Hypotheses: Theoretical Explanations

Leadership behavior. The data for Hypotheses 1a and 1b support the contention that the performance of task leadership behaviors is a common source of both high participation and leadership status. The mean value of the leadership–participation rate correlations with task leadership measures was .69, whereas the mean for the maintenance measures was only .16, $t(70) = 6.37$, $p < .001$.

The means for subcategories of functions were as follows (the first three categories include maintenance leadership): (a) .017 for negative social interaction, (b) .178 for general maintenance measures (e.g., liking), (c) .180 for positive social interaction, (d) .390 for seeking information and structure, (e) .615 for initiating structure and procedure, (f) .722 for giving information and opinions, (g) .735 for problem identification and solving, (h) .736 for the general measures of leadership, and (i) .841 for general measures of task leadership.

As hypothesized (1b), the association between leadership and participation was significantly correlated with ratings of the breadth of the task leadership measures, $r = .36$, $p < .01$. However, the correlation was only .13 when the entire sample of 72 values was used. This lower value is consistent with the notion that the maintenance behaviors are not the source of the leadership–participation rate relationship.

Task skill. A positive relationship was predicted (Hypothesis 2) between task skill requirements and the association between participation and leadership. The data are supportive. The variables were correlated .27 ($p < .01$) for the total sample and .35 ($p < .01$) for the task subsample.

Sexual status. A significantly higher leadership–participation correlation mean was found for mixed-sex groups than for same-sex

Table 3
Means and t *Values for Dichotomous Variables*

Note. All *t* values were calculated with pooled error terms and with 70 degrees of freedom. The means are correlational values, not Fisher *z* scores.
* $p < .05$. ** $p < .01$. *** $p < .001$.

groups in the total sample, $t(70) = 3.18$, $p < .01$, and the subsample of task measures, $t(55) = 5.68$, $p < .001$. The means for male and female groups were almost identical (see Table 3). Unfortunately, the mixed-sex variable is confounded with type of task. Thirty-one of the 34 correlations for mixed-sex groups were from groups assigned opinion tasks. These 31 correlations constitute most of the data points (34) for opinion groups. Consequently, it is impossible to know which of the two variables is creating the significant result. The confound remained when the maintenance leadership measures were removed.

Demand characteristics. The leadership–participation correlations based on data from subjects aware of being observed were not significantly higher than those from unaware subjects for the total sample, $t(70) = .88$, or for the subsample, $t(55) = .61$.

Tests of the Hypotheses: Situational Parameters

Group size. A higher association between leadership status and participation was predicted for larger groups (Hypothesis 5). The group size ranged from 3 to 18 members, with a mean of 4.8. The moderate correlations between group size and the dependent measure for both the total (.39) and subsample (.45) were significant ($p < .01$).

Observer ratings. The hypothesis (6) that leadership–participation correlations would be higher when based on observer ratings than when based on peer ratings or self-ratings was not supported. Although the means were in the predicted direction, the difference was not significant for either the total sample, $t(70) = 1.30$, or for the subsample, $t(55) = 1.70$.

Exploratory Analyses

As mentioned above, a large number of independent variables, related to the groups, their tasks, and the leadership measures used, were included for exploratory analyses. The authors recognize that because of the nature of such procedures, the findings may be due to chance and may not be real effects. For this reason, these results are presented only as possible relationships that merit further investigation.

Differences due to the type of task were examined by a one-way analysis of variance. Although the resulting F for the entire sample was not significant, $F(3, 86) = 2.02$, $p = .12$, the value for the task subsample was $F(3, 53) = 5.92$, $p < .001$. Using a Duncan multiple range, the mean for opinion groups was found to be higher than the other means (problem solving, verbal production, and manipulation). As indicated above, the groups assigned opinion tasks were predominately mixed-sex groups. Consequently, either sexual composition or the type of task could be creating the results.

The two measures of motivation (intrinsic interest and external motivation) and the extent to which the task was intellectual were correlated with the degree of association between leadership status and participation (see Table 2).

The interchange before the first leadership measure ranged from 1 minute to 4 hours with a mean of 42 minutes. The time prior to the last rating varied from 5 minutes

Table 4
Stepwise Regression Analysis for the Entire Sample and for the Task Subsample

Statistical parameter	All values	Task subsample
Multiple R	.792	.801

df	4/67	5/51
Constant (Fisher z)	.816	.303

* $p < .01$.

to 24 hours, with a mean of 95 minutes. A low but significant positive correlation was found only between the dependent measure and the time elapsed prior to the first leadership measure for both the total sample and the subsample (Table 2).

Only six of the correlations involved leadership ratings that had practical significance for the group members. They were from studies which used the same methodology (Burroughs & Jaffee, 1969; Jaffee & Lucas, 1969). The six correlations were significantly lower than the others in the task subsample, $t(55) = 3.33$, $p < .001$.

Multiple Regression Analysis

Stepwise multiple regression analyses were performed to determine the amount of variance in the leadership–participation Fisher z scores accounted for by the 28 independent variables. The analyses for the entire sample and for the subsample are summarized in Tables 4 and 5. The B coefficients are for nonstandardized measures; the beta values are for standardized scores.

For the entire set of leadership–participation correlations, the multiple R was .792, accounting for 63% of the variance. The largest coefficient was a negative value for maintenance functions. The inclusion of this variable and the ratings of the breadth of the leadership measures support the task leadership activity explanation. The contribution of the mixed-sex measure supports the view that the leadership–participation relationship is due in part to the sexual composition of the group. The inclusion of the observer ratings supports the observer bias hypothesis. Because the maintenance functions were excluded from the subsample, the strongest predictor for the entire sample was removed from the second analysis. The multiple R was .801. The first three variables to be included were added in the same order as in the total sample analysis. Two additional variables were included, all male groups versus other sex composition groups, and groups of college students versus noncollege subjects.

Conclusions

Three major explanations for the leadership–participation rate relationship were supported by the data analysis: (a) task leadership behaviors are a component of total participation and a basis for leadership status; (b) those with superior task ability make more task-related contributions to the group, which increases their participation; and (c) males are permitted both greater influence and higher participation rates (although the sex differences were confounded with group differences). These explanations can be inte-

grated if the performance of task leadership behaviors is viewed as the major source of the variance common to leadership status and participation rates. Competency and sexual status can be considered as variables that moderate the performance of such behaviors. Behavioral manifestations of competency (such as giving information and proposing solutions, procedures, and structure) are in themselves task leadership behaviors. In addition, members of new groups who feel they are competent make more influence attempts, whereas members who realize that they are less competent make fewer leadership attempts (Hemphill, 1961). The literature on sex differences indicates that males are considered to be more influential, talk more often, and perform more task leadership acts.

The suggestion is made from several points of view that the quality and frequency of members' contributions are correlated. For example, theories of emergent leadership postulate that those who have established their competency are allowed greater influence as the group continues (Bales, 1953; Stogdill, 1959). Hoffman and Clark (1979) report positive correlations between the group members' total participation and the extent to which they contributed to the adoption of the solution.

Some of the explanations of the leadership–participation rate relationship that are based on within-group differences (such as personality traits and motivation) could not be tested in this study. However, the performance of task leadership behaviors can be offered as an alternative to Sorrentino and Boutillier's (1975) assertion that differences in group members' motivation explain the leadership–participation rate relationship. They found participation rates, but not the quality of the solution offered by the confederates, to be related to peer ratings of task leadership. Sorrentino and Boutillier suggested that the high participants received higher leadership ratings because they were perceived to be more motivated. However, in manipulating participation rates, Sorrentino and Boutillier held constant the proportion, but not the frequency, of the types of behavior performed by the high and low participant confederates, thus confounding task behaviors with total participation. Consequently, the higher participants may have been rated higher in task leadership because the group members recognized their performance of more task leadership acts.

Our analyses suggest that the *high* correlation of task leadership and participation may be cautiously generalized to real groups. Almost all of the findings are from formally leaderless groups. The relationship between the two variables is lower if the leadership ratings have practical implications for group members and if the groups are not comprised of college students. These variables were also confounded with task differences, which makes it more difficult to generalize the strength of the leadership–participation rate relationship to a variety of real-world tasks. The degree of association between leadership and participation was also lower when the leadership judgments were not made by observers. In addition, for all but two of the correlations analyzed, less than 45 minutes had passed before the first leadership measure was taken.

Additional research is warranted in several areas:

1. The generalizability of the leadership–participation rate relationship needs to be explored.

2. Predictive research is needed to determine if the performance of task leadership behaviors actually serves as the basis for the common variance between leadership and participation and if it is moderated by sexual status, competence, and motivation.

3. Although it is clear that task leadership status and participation covary, the causal relationship between the variables is not clear. Perhaps high participation precedes emergent leadership status. Or perhaps, as the leadership valence theory (Stein et al., 1979) suggests, the attainment of leadership status occurs almost simultaneously with acts of participation. According to that theory, the leadership status of a member is enhanced by each successful attempt to influence others.

4. The relationship of participation rates to formal leadership status has not been examined. The roles of formal leaders may require that they speak more often than others (Burke, 1974). When the formal roles require

the performance of task leadership behaviors, such behaviors could be the basis for both high participation and judgments of the extent to which an individual actually leads the group.

Environmental Determinants of Memory Improvement in Late Adulthood

Lynn Spitzer
Yale University

Two studies were conducted with nursing home residents to determine whether memory could be improved. This was accomplished by increasing the cognitive demand of the environment and then varying the extent to which residents were motivated to attend to and remember these environmental factors. In Study 1, motivation to practice recommended cognitive activities was manipulated by varying the degree of reciprocal self-disclosure offered by interviewers in a series of dyadic interactions. In Study 2, motivation to practice recommended cognitive activities was manipulated by varying whether positive outcomes were contingent on attending to and remembering these activities, which increased in demand over time. Whether as a function of interpersonal (Study 1) or practical (Study 2) incentives, engaging in cognitive activity resulted in improvement on standard short-term memory tests, including probe recall and pattern recall, as well as in improvement on nurses' ratings of alertness, mental activity, and social adjustment for experimental groups relative to controls.

Arguments and counterarguments over evidence purportedly showing age-related intellectual and cognitive decline have been made with great vigor (cf. Baltes & Schaie, 1976; Horn & Donaldson, 1976; Horn & Donaldson, 1977). Moreover, there is disagreement about what the deficits might be, if they do exist. Let us take memory as an example. Adamowicz (1974) found short-term memory decrements at the encoding and postcoding phases but not at the retrieval phase, whereas Anders and Fozard (1973) basically found retrieval deficits. Drachman and Leavitt (1972) suggested that the major cause of memory deficiency for the elderly lies not in a deficit in retrieval but in a disorder of storage. Yet another view is that of Eysenck (1973), who suggested that the decrement is primarily in the decision process and not in retrieval.

In this article we do not wish to question whether there is memory decline with advanced age. Instead, we ask to what the decline may be attributed when it does appear. Thus, rather than looking for either a description of the memory deficit (as in the studies previously cited) or methodological artifacts that may explain away purported differences (cf. Baltes & Schaie, 1976), we suggest another focus of analysis: one in which deficits are seen as real and one in which environmental factors are seen as influencing and masking cognitive abilities of the elderly. Our position is basically that social and environmental factors may impact on memory directly, leading to real deficits that may only look as if they are biologically determined because they are age related.

How might social factors directly impact

This research was supported by Grant BNS 77-24159 from the National Science Foundation to the first author. The authors are grateful to the directors and staffs of the Arden House and Florence Nightingale nursing homes for their permission and cooperation in conducting the two studies.

on cognitive processes? The elderly, especially those residing in institutions, are a population who are by and large confined to a very restricted living space. Such restriction, arising from social system factors and physical ailments orthogonal to direct brain deterioration, may have far-reaching effects on cognitive processes. For these people, every day is like every other day. Moreover, for those residing in institutions, every room is like every other room, and each person seen today is the same as each person seen yesterday and the day before. Living in such highly redundant environments leaves one with little information to process. As a result, the ability to think and remember may diminish. During the earlier part of one's life, it may be an efficient strategy to try to minimize informational input when living in a demanding and overstimulating environment. Over the years one may have successfully taught oneself to tune out much of the environment in order to function more adaptively (cf. Langer, 1978; Langer, Note 1) only to find that in later years such proficiency has become maladaptive.

After years of learning how to avoid expending cognitive effort, a person might find it difficult to know how to reverse the process when faced with little to think about and little to do. Yet it seems that reversal is possible at least in some areas. In earlier research (Langer & Rodin, 1976; Rodin & Langer, 1977) we found that making more demands on the decision-making abilities of institutionalized elderly adults had the effect of improving health and psychological well-being and tended to be related to lower mortality rates as well. In the present studies we consider whether improvements in memory might also result from changes in the social psychological environment.

If cognitive abilities do diminish at all with disuse, then practice in thinking over time may be successful in reversing the debilitations. However, if people have been implicitly led in the ways outlined above to avoid expending cognitive effort, then more than a mere suggestion to expend this effort would seem necessary to motivate them to do so. The following studies were undertaken with these two considerations in mind. In both studies we attempted to motivate subjects to adhere to a recommended course of action over time that asked them to think about various issues. Encouraging this commitment to increase cognitive activity was accomplished in the first study by providing the opportunity for reciprocal self-disclosure between the subject and an interviewer who recommended the particular course of cognitive activity.

According to Janis and Rodin (1979), eliciting self-disclosure is one factor that is critical in helping a person to establish referent power (French & Raven, 1959) that promotes commitment to recommended courses of action. Persons have referent power for those who perceive them as likeable, benevolent, admirable, and accepting. Their motivating power derives from this source. Rodin and Janis (1979) have described how the use of referent power in health care settings promotes internalization of medical recommendations made by health care professionals. Because no coercive inducements are used to motivate the person, Rodin and Janis hypothesized that the use of referent power increases the likelihood that persons will feel personal responsibility in adhering to prescribed regimens. To establish referent power that motivates persons to commit themselves to recommended courses of action, an individual first must encourage them to disclose their personal feelings, troubles, or weaknesses (Janis, in press; Quinlan, Janis, & Bales, in press). Demonstrated willingness to engage in reciprocal self-disclosure is effective in this regard (cf. Jourard, 1971).

We obtained a commitment to increase cognitive activity in the second study by introducing a contingency whereby greater cognitive effort resulted in greater tangible reward. In both studies, we hypothesized that relative to control groups, increased cognitive activity in experimental groups would promote more efficient performance in cognitive areas such as memory.

Study 1

In this study we used a series of reciprocal self-disclosure conversations as an incentive

for adhering to a particular course of recommended cognitive activity. The cognitive activity involved remembering a series of questions and searching the environment and one's long-term memory for information relevant to their answers. A low-self-disclosure group was included to control for the amount of time spent with an interviewer discussing past and present events. This more standard interview procedure, however, was not expected to provide sufficient interpersonal incentive to occasion the kind of commitment necessary to stimulate renewed cognitive activity. To control for changes that may have occurred simply because of multiple administrations of the memory tests, a no-treatment group was added to the design.

Method

Subjects

Fifty-four middle-class ambulatory residents of a private suburban nursing home participated in the study. Residents who were judged by the institution's head social worker to be at least somewhat alert took part in the study. The average length of stay for the sample was 2.8 years. All participants could eat their meals in the dining room without assistance. Subjects were matched on age, length of time in the nursing home, social worker's ratings of alertness, and sex and on this basis were assigned to one of four groups: high reciprocal self-disclosure ($n = 10$, M age $= 80.4$); low reciprocal self-disclosure ($n = 20$, M age $= 79.6$); pretest and posttest only (for no-interview controls, $n = 14$, M age $= 78.9$); and pretest only (for test-instructions subjects, $n = 10$, M age $= 78.8$).[1]

Procedure

All subjects were visited 1 month prior to the experimental treatment period by an experimenter who administered an interview and the memory tests described below. She did not participate in any of the interviews and was blind to experimental conditions to which subjects had been assigned.

In both experimental conditions, subjects were subsequently visited a total of four times by one of five interviewers (four males, one female) during the course of a 6-week period. Each interviewer visited subjects in both experimental conditions. None of them knew about the memory pretest and posttest, and all were blind to the experimental hypothesis regarding memory. Visits were spaced so that there was at least 1 week between the visits. Interviewers were instructed to keep the length of each visit between 30 and 40 minutes. At the beginning of the first session, residents were told that the interviewers would be coming for about 6 weeks.

The interviewers introduced themselves as college students who were interested in getting to know people who were much older than themselves. The interviewer told the subject that he or she would like to get together once a week with the participant to talk. If the person agreed, the interviewer began a discussion. The nature of the discussion was determined by the condition to which the subject had been assigned. At the end of each visit, the interviewer told the subject that he or she would return in approximately 1 week.

High-reciprocal-self-disclosure group. In this condition the interviewer began the first visit by stating that "one of the things I never get to do is to tell someone older than I am the kinds of things I am doing and thinking about." In each of the four visits the interviewer began the visit by talking about events that were occurring in his or her own life (e.g., school, family, jobs) in a largely unstructured way, with the only requirement being that she or he let the resident talk whenever she or he wanted to. At the end of each visit, the experimenter suggested specific topics about which subjects were asked to think. These were to be discussed on the next visit.

Low-reciprocal-self-disclosure group. Here the interviewer began the discussion by stating that "one of the things I never get to hear very much about is what people who are older than I am are doing and thinking about." The questions asked during this and subsequent visits were concerned with current occurrences and events, both personal and public (e.g., what was going on that day, families). The interviewer was instructed to ask questions, comment appropriately, and listen attentively and interestedly. At the end of each visit, the experimenter suggested specific topics about which subjects were asked to think. These were identical to those suggested to high-disclosure subjects and were to be discussed on the next visit. This standard interview procedure was typical of the kinds of interviews older people in nursing homes experience.

No-treatment group. Subjects in this condition were not visited by the interviewers, but received the same memory pretest and posttest as the above two groups.

Dependent Variables

Two types of measures were used to assess the effects of the experimental manipulations. The first measure, a questionnaire, was responded to by the nurses who staffed the floors on which the subjects lived; the nurses were unaware of the experimental hypotheses and treatments. The questionnaires were completed at two different times—once before the experimental manipulations were introduced and again several weeks after the experimental treatments

[1] Only those subjects who were available for each interview session were included in the final sample.

had ended. The questionnaires included 10-point scales that asked for ratings of how happy, alert, dependent, sociable, and active the residents were.

The other measures were two types of memory tests administered 1 month prior to and 1 week after the experimental treatments. To minimize the anxiety that is often felt by the elderly when presented with testlike situations, the tests were not described as such. Instead the experimenter introduced herself as an individual interested in finding out what changes might be made to make the nursing home "a more pleasant place for the people who live here." She then asked subjects for their suggestions as to what changes they would like to see made. After the subjects made their suggestions, the experimenter requested that they give their opinion on some new ideas that the experimenter had come up with. The two memory tests were disguised as a new activity or procedure that might be instituted in the nursing home. The subjects "tried out" these "new activities and procedures" and offered an opinion of each. The order in which the tests were presented was systematically varied.

The two tests used were pattern recall and probe recall. Pattern recall is a test of immediate recall of visual patterns. The subject is required to watch the experimenter tap a set of four blocks in a certain order and to repeat those exact movements immediately afterward. As the test proceeds the series of items (each block pointed to is considered an item) increases in length. The score reflects the length of the series a subject is capable of imitating.

In probe recall, a test that measures short-term memory of paired items, photographs of five people were shown to the subject, and each photograph was paired with a person's name. The photographs were then presented again at various intervals throughout the test. Subjects were required to recall the name associated with each photograph. To make this test relevant, pictures were used of elderly people who, subjects were told, might be coming to the nursing home.

Both tests had two equivalent forms, with split-half reliability and/or test–retest reliability ($rs = .86$ and .88, respectively) allowing both premanipulation and postmanipulation measures to be taken. Approximately one half of the subjects in each condition received Form A of the tests for the pretest and Form B for the posttest, whereas the other half received them in the opposite order. We predicted that greater practice in thinking would result in higher scores on these measures for the high-reciprocal-self-disclosure group relative to the remaining groups.

As a secondary goal of this experiment, we were interested in determining whether making the tests relevant and nonthreatening in this way would actually have an effect on test performance, since test anxiety alone may impair performance. Therefore, we also included for comparison another no-treatment group of similar nursing home residents, who were given the pretest measures only and were told that they were memory tests rather than "new activities."

Results

Analyses of pretest scores on both reca tests and of nurses' ratings revealed no signi icant differences among the three groups a hence demonstrated group comparability the start of the experiment (all $Fs < 1$).

Table 1 presents group means and chan scores on the recall tests as a function of t experimental treatment. Analyses of varian for both tests individually showed significa differences among the groups: for patte recall, $F(2, 41) = 3.25$, $p < .05$; for pro recall, $F(2, 41) = 3.92$, $p < .05$. Individu comparisons revealed that whereas the hi reciprocal-self-disclosure group showed i proved memory relative to controls on b tests, the low-reciprocal-self-disclosure gro was not reliably different from the no-tre ment group. In addition, pretest–posttest co parisons on the pattern recall test showed th there was significant improvement for t high-self-disclosure group, $t(9) = 2.36$, p .05, but no significant change for the low-se disclosure group or for the control group. Si ilar analyses for the probe recall test revea not only that the treatment improved memo for the high-self-disclosure group, $t(9)$ 3.46, $p < .01$, but also that when there was treatment or minimal treatment, memory clined significantly in as short as 6 wee time: for no treatment, $t(12) = 2.29$, p .05; for low self-disclosure, $t(18) = 2.18$, p .05.

A fourth group of residents were also giv the memory tests ($n = 10$). For them t tests were presented as memory tests and we not integrated into the nursing home conte A comparison of this group's scores with t scores for subjects in all the other groups co bined ($n = 44$) was conducted to assess t effects of test context. Subjects in the tes concealed groups scored significantly bett (pattern recall $M = 4.0$; probe recall M = 10.1) than subjects in the test-unconceale group (pattern recall $M = 2.4$; probe recal $M = 5.3$), $t(52) = 2.01$, $p < .05$; $t(52)$ = 2.68, $p < .02$, respectively.

After each interview, the interviewers rate residents for amount spoken during the inter view, percentage of items initiated for discus

Table 1
Study 1: Mean Change Scores (Posttreatment Minus Pretreatment) on Memory Tests for Each Experimental Condition as a Function of Level of Involvement

Group	Memory test					
	Pattern recall			Probe recall		
	Pre	Post	Change	Pre	Post	Change
High reciprocal self-disclosure	4.7	6.7	2.0_a	10.0	15.3	5.3_a
Low reciprocal self-disclosure	4.0	3.3	$-.7_b$	12.2	9.2	-3.0_b
No treatment	4.8	4.6	$-.2_b$	11.5	9.0	-2.5_b

Note. Different subscripts within each test indicate significant differences at $p < .05$.

sion, and how friendly they were to the interviewer. The high-reciprocal-self-disclosure residents spoke on the average for 70% of the interview and initiated 75% of the items for discussion. By comparison, the low-self-disclosure subjects spoke for an average of 45% of the interview and initiated only 30% of the items for discussion. The groups were not rated differently in how friendly they were to the interviewer. There were also no reliable differences between conditions in the length of interviews, and all interviews became longer over the 4 weeks.

The next analyses of variance were performed on the nurses' ratings. These results reveal that the greater practice in thinking initiated by the high-reciprocal-self-disclosure treatment not only influenced short-term memory but produced general social psychological effects that were discernible to nurses, who were unaware of the experimental treatment. As can be seen in Table 2, the high-involvement group was rated as being more aware, more active, and more self-initiating than the no-treatment group (all ps $< .05$). Although the low-involvement treatment appears to have resulted in nurses' judgments of a greater self-initiating attitude, on other measures the low-involvement group was not significantly different from the no-treatment group.

Table 2
Study 1: Nurses' Mean Ratings (Posttreatment Minus Pretreatment Scores) of Residents' Behavior by Experimental Condition

Group	Mood	Awareness	Sociability	Activity	Self-initiating	Alertness	Health

Discussion

The results of Study 1 suggest that memory can be improved when the elderly are motivated to commit themselves to a recommended course of action that involves increased use of their cognitive abilities. Because people in the high-reciprocal-self-disclosure group spoke more and initiated more topics for conversation than their low-self-disclosure counterparts during the 6-week period of the study, they appear to have been more involved in the substance and conduct of the interviews. This greater involvement apparently led to a greater commitment to follow the interviewer's recommendations to think about a variety of proposed topics for future discussion. Although the low-involvement group also was asked to think about things to be discussed in between the scheduled visits, the character of the interaction was not sufficiently involving to encourage them to make a commitment to do so. Participants were not judged to be more friendly in any one treatment condition, suggesting that increased thinking and not simply greater liking for the interviewer was responsible for the results obtained. In addition, the items on which the high-self-disclosure group increased on the nurses' ratings (aware, active, and self-initiating) also seem to reflect a general increased involvement with the environment.

It is significant to note that the memory tests used were measures of short-term recall, in which there has been strong but by no means unequivocal evidence for age-related decline. The study suggests that such decline is not inevitable and that it can be strongly affected by environmental–social processes. However, we can only infer that the subjects actually followed the recommended cognitive activity as a result of the high-reciprocal-self-disclosure treatment and that this led to the memory improvement. Therefore, a second study was designed to increase, in a very different way, the likelihood that subjects would exercise their cognitive abilities.

Study 2

Whereas the first study provided interpersonal incentives for increased cognitive activity, in the present study practical incentives were employed. An experimental group for whom positive outcomes depended on remembering was compared with a group for whom positive outcomes were not contingent on memory and with a no-treatment control group. We predicted that the contingent group would engage in more cognitive activity that would result in improved memory.

Method

Subjects

Forty-five middle-class residents of a second nursing home participated in this research. The average length of stay for the sample was 3.4 years. There were 14 subjects (M age = 80.62 years) in the contingent group, 16 subjects (M age = 76.19) in the noncontingent group, and 15 subjects (M age = 80.73) in the no-treatment control group. Only those residents who had been judged on an 11-point scale by the institution's head nurse to be at least somewhat alert (contingency $M = 7.77$, noncontingency $M = 7.13$, and no-treatment $M = 8.33$) served as subjects. Though residents varied greatly with respect to their particular medical concerns, to participate in the investigation they had to be healthy enough to be ambulatory. Thus, there were no initial group differences with respect to social class, age, alertness, and general health. Similarly, no initial mood differences were revealed on an 11-point scale of self-reported happiness (contingency $M = 5.21$, noncontingency $M = 5.58$, and no-treatment $M = 5.53$).

The experiment was conducted by seven female experimenters who were blind to the study's hypothesis.

Procedure

The residents in the two experimental conditions were visited a total of nine times over the course of a 3-week period, with various cognitive demands made during each visit. The visits were spaced such that the amount of time in between visits increased over the 3 weeks, thereby increasing the demands on subjects' memories over the course of the study. Those in the no-treatment condition were visited only on the first and last day of the study (when the memory tests were administered). Memory tests (described below) were given 2 days after the ninth visit.

After introducing herself, the experimenter told each resident that she was a student who was interested in learning about life in a nursing home. She explained that with the person's permission, she would like to come several times during the next 3 weeks to discuss certain things with him or her. To insure that the relationship from the resident's per-

spective was time bound, she indicated that she would have to return to school after 3 weeks but that they could correspond if the resident so desired. The nature of the subsequent interaction was a function of the condition to which the resident had been assigned.

Contingent condition. Residents in this condition were told that they were going to be asked several questions during each visit and that they would receive one poker chip for each correct response. The experimenter explained that at the end of the 3 weeks they would be able to redeem the chips for a gift and that the more chips they had the better the gift would be. The experimenter then asked the resident a few questions about that day's meals and activities. The first questions asked were made simple enough to insure that everyone received at least one chip on the first visit (e.g., "Did you eat breakfast today?"). The residents were then asked two questions that required them to seek information from their immediate environment. If they did not know the answer, they were told they would be asked again on the next visit. On the first visit, the questions were "Do you know the names of any of the nurses?" and "Do you know the name of another resident?" Subsequently, each individual was asked three such questions per visit.

The assumption, which proved correct, was that the resident would not know the answer to at least one of the questions when first asked and would therefore have to engage in an information-seeking process before the next visit. The questions were of varying levels of difficulty, but they all concerned life in the institution (e.g., "How many different nurses' and patients' names do you know?", "What activities were there today?", "When will the next cocktail party/bingo/concert take place?", and "Approximately how many male residents are there on this floor?"). Although the information-seeking questions kept changing, residents were asked what they ate for breakfast and lunch that day, what they ate for dinner the night before, and what activities they engaged in during that day on each visit.

At the end of each visit, before departing, the experimenter told the resident, "Please try and remember everything you do today and also find out . . . [e.g., when the next bingo game will take place]. I'll be returning on . . . [day specified] to talk to you and will give you more chips for more answers." Thus, each subject had to remember what information to seek out, to actively seek it, and then to remember it until the experimenter's next visit. Each question was asked on three consecutive visits unless the resident knew the answer sooner. If on the third visit the resident still did not know the information, the question was not asked again.

On those questions for which it was impossible to make an immediate determination of accuracy (e.g., what the person ate for breakfast), the answers were taken at face value, and the residents in this condition received a chip every time they replied to a question. Since persons in all conditions in the study at several points said "I don't remember" in response to questions asked and the answers given were accurate much more often than not in the cases that could be checked, this assumption of accuracy seemed reasonable.

Noncontingent condition. The substance and the form of the visits in this condition were exactly the same as those in the contingent condition. The only difference between the noncontingent condition and the contingent condition was that the residents in the former were told that they would be given chips as mementos of each visit, the number of which would depend on how many the experimenter had with her that day. The residents in this condition were told that the chips would be redeemable for a gift in 3 weeks. Each subject in this condition was yoked to a subject in the contingent condition for number of chips and length of interview.

No-treatment condition. These residents received an initial visit by the experimenters and were asked the same questions as the residents in the contingent and noncontingent conditions. At the time of this first visit, they were told that the experimenter would return to speak to them in 3 weeks and on that occasion, in return for cooperating with the project, they would each receive a gift. This was done to control for the possible effects of anticipating some positive future outcome. They were not visited again until the measures were taken.

Dependent Variables

Four days after the last visit all subjects were given a test of immediate memory and a test of memory for remote events by an experimenter with whom they had no previous contact. The test of immediate memory used was a probe recall measure in which test words varied in terms of how many new words were presented between the first presentation of the test word and its repetition. There were approximately 5 sec in between the presentation of each word. After the test was administered, the experimenter also asked the residents several questions concerning remote past events (e.g., "When did the Great Depression occur?"; "Where is the Empire State Building?"; "How long has television been around?"; and "What were the names of your neighbors before you moved here?"). Subjects in the contingent and noncontingent groups also were asked how much they liked the woman who had visited them, whether they remembered her name, and approximately how many times they had been visited by her.

Responses to questions asked during visits to subjects in the contingent and noncontingent groups allowed for a comparison of memory for recent events between these two groups over time. These questions fell into two categories: memory for events they had experienced (e.g., meals and activities) and memory for information they had to seek out and remember (e.g., how many male residents there were in the nursing home).

In addition to these measures, with informed con-

sent, each resident's medical records were examined and all entries regarding the following aspects of the person's medical condition were recorded: medications, major tranquilizers, vital signs, complaints, and social adjustment.

Results

The major questions addressed in this study were whether giving people a reason to remember would commit them to greater cognitive activity and, if they were committed, whether the beneficial effects would generalize to other memory processes. Before looking at generalization effects, we felt it important to see if the training was effective. That is, did the contingent group show signs of improvement for the things on which the contingency was focused? A comparison of memory for meals and activities over time suggests that the contingency treatment was indeed effective. A repeated measures analysis of variance for meals remembered over time yielded a significant effect for contingency, $F(1, 28) = 4.23$, $p < .05$.[2] Of a maximum of three, the contingent group remembered an average of 2.76 meals, whereas the noncontingent group remembered an average of 2.20. The Group × Time interaction was also significant, $F(8, 224) = 2.66$, $p < .01$ (Winer, 1971). Whereas there was no difference between the two groups on the first visit, the contingent group remembered significantly more meals than the noncontingent group for each visit after the first. The difference between the first and last visits for the contingent group was also significant, $t(13) = 2.94$, $p < .02$. However, there was no difference between the first and last visit for the noncontingent group.

In addition to improved memory of meals over time, subjects in the contingent condition took less time than subjects in the noncontingent condition to find out the required information regarding activities in the nursing home. Obviously, only those subjects who did not know the answers upon being asked the first time were included in this calculation, since we were interested in subjects finding out and remembering information they did not already know. (There was no initial difference among the groups with respect to this knowledge.) Those who knew the answer by the second time they were asked were given a score of 3, those who obtained the information after being asked three times were assigned a weight of 2, and those who only knew the answer after four visits were assigned a weight of 1. The mean weighted total over all the target questions was 12.40 for the contingent group, compared with only 8.25 for the residents in the noncontingent group, $t(28) = 2.62$, $p < .05$.

Attitudes toward the interviewer and the visits also were assessed. Although each group received a total of 9 visits, the contingent group estimated that they had received an average of 13 visits, and the noncontingent group estimated an average of 6 visits. Eighty-two percent of the contingent group *over*estimated the number of visits, whereas 73% of the noncontingent group *under*estimated the number of visits, $\chi^2(1) = 6.60$, $p < .05$. Both groups were also asked to indicate on a 10-point scale how much they liked the person who had visited them. The results indicated that all participants claimed to have liked the experimenter; the mean for the contingent group was 9.92, compared with 7.93 for the noncontingent group, $F(1, 26) = 7.18$, $p < .02$. Residents were also asked if they remembered the name of the person who had visited them. Sixty-nine percent of the contingent group remembered, compared with 53% of the noncontingent group. Although in the predicted direction, this difference was not statistically significant.

Probe Recall Test

To test whether training in remembering recent events would generalize to improvement in immediate memory, scores on this test were compared for the three groups. Out of a possible score of 10, the mean for the contingent group was 7.50, compared with 4.57 and 5.83 for the noncontingent and no-treatment groups, respectively, $F(2, 36) = 6.55$, $p < .01$. A Tukey test showed that the contingent group was significantly different from

[2] All subjects were not available when each measure was taken. Therefore the degrees of freedom vary from measure to measure.

the noncontingent group ($p < .05$) and the no-treatment group ($p < .05$). The latter two were not different from one another. This finding is especially impressive in light of the fact that the residents were not rewarded for answering these questions; nor were the experimenters who administered the test previously known to them.

Remote Events

Immediately after the probe recall test was administered, subjects were asked questions regarding remote past events (e.g., "When was the Great Depression?" and "How long has television been around?"). Again, significant differences emerged. Responses were coded by an individual who was unaware of the conditions to which subjects had been assigned. The mean number of correct answers for the contingent group was 2.46, compared with 1.53 and 1.54 for the noncontingent and no-treatment groups, respectively. A contrast that set the contingent group as greater than the remaining two groups, which were set equal to one another, was significant, $F(1, 38) = 7.42$, $p < .01$.

Medical Chart Data

The social adjustment comments recorded on residents' medical charts by the nursing home staff were rated on a 7-point scale, in which higher numbers indicated improvement from 1 week before the first visit to 1 week after the last measures were taken; a score of 4 signified no change. These ratings were made by an experimenter who had training as a nurse and who was blind to the purposes of the study and to the groups to which the subjects belonged. The mean score for the contingent group was 5.00, showing some improvement, compared with 3.79 for the noncontingent group and 3.87 for the no-treatment group, both of which showed slight decrements on this measure, $F(2, 40) = 5.41$, $p < .01$. A Tukey test indicated that the contingent group was significantly different from the other two groups ($p < .05$ in both cases), which were not different from one another.

Data on residents' vital signs showed the same pattern as above, although the ratings were not significantly different for the three groups (4.31, 4.29, and 4.21 for contingent, noncontingent, and no-treatment groups, respectively). There were also no reliable differences in the amount of medication taken. However, differences did emerge in regard to the amount of complaints about physical discomfort that residents voiced. The mean rating, on a 7-point scale (higher numbers indicate more complaints), for the contingent group on this measure was 5.07, compared with 3.64 and 3.80 for the noncontingent and no-treatment groups, respectively, $F(2, 40) = 8.14$, $p < .001$. Again, a Tukey test showed the contingent group to be different from the other two ($p < .05$ in both cases), which were not different from one another. As in Langer and Rodin (1976), complaints were taken as a positive sign—when one feels one can have an effect on the environment, complaining makes sense; when one has given up, it does not. Subjects on whom demands were made, in turn, appeared to be more likely to make demands on their environment.

Discussion

Those residents for whom outcomes were contingent upon memory showed cognitive improvement relative to those to whom the same amount of attention was given without contingent rewards for cognitive activity. Increasing the use of cognitive abilities in this way, that is, making remembering matter, had several generalized effects on memory. It improved short-term memory, as evidenced by performance on the probe recall test, improved memory for recent events, as evidenced by better recall of meals and activities, and resulted in greater speed in finding and reporting information that was to be ascertained from the environment. It also significantly improved social adjustment.

It appears that having this responsibility for outcomes was subjectively a positive experience. Residents in the contingent condition overestimated the number of visits they had received and also expressed greater liking for the visitor than did the comparison group.

Conclusion

Both studies provided either interpersonal or practical incentives for becoming more involved with the environment and for greater attention to and remembering of environmental events. We found that restructuring the environment to make it more demanding and then motivating people to increase their cognitive activity seem to lead to improvements in memory that are generalizable. It is critical to note that the interviews in no way provided explicit training for the types of memory tests that constituted the dependent variables of greatest interest; nonetheless, performance for experimental subjects showed reliable improvement.

Perhaps one could argue that the improvement in performance for the high-reciprocal-self-disclosure group in Study 1 and the contingency group in Study 2 was due solely to an increase in motivation to perform well and not to improved ability through increased practice. However, the greater recall over time demonstrated in Study 2 suggests that real improvements did take place. Although this alternative explanation can never be ruled out completely in this or any other study, for that matter, that finds performance differences, if one never has the motivation to exercise one's ability, the motivation/ability distinction becomes a moot point. Although this general issue has been most directly argued with regard to racial differences and IQ (e.g., Loehlin, Lindzey, & Spuhler, 1975), the same can be said of age differences and some cognitive abilities. Again, like findings in which race and IQ are considered, the data from Study 1 suggest that the context in which the measures are given, such as whether they are labeled as memory tests, also affects motivational performance. Taken together, these findings suggest that psychologists must be sensitive to the social–environmental factors that can influence not only performance in the testing context but, ultimately, the desire to practice and perform in general.

Though the present studies were not aimed at determining the extent to which memory loss in the elderly is environmentally rather than biologically determined, the present investigations coupled with other studies examining the effects of environment on intelligence in the elderly (e.g., Plemons, Willis, & Baltes, 1978) suggest that the impact of the environment may be profound. The significance of these factors for memory, and cognitive ability more generally, suggests that studies explicitly designed to test for age-related deficits must control for differences in environmental variables.

Instructions for Submission of Manuscripts

Papers submitted to the *Journal of Personality and Social Psychology* after April 1, 1979 will be considered under new policies approved by the Publications and Communications Board. Effective with the 1980 volume of the journal, the following policies will apply:

The *Journal of Personality and Social Psychology* publishes original papers in all areas of personality and social psychology. It emphasizes empirical reports but may include specialized theoretical, methodological, and review papers. Beginning in April 1980, the journal will be divided into 3 independently edited sections: ATTITUDES AND SOCIAL COGNITION, INTERPERSONAL RELATIONS AND GROUP PROCESSES, and PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES. Authors should submit manuscripts to the appropriate section editor according to the section definitions and manuscript preparation instructions provided on page 468 of the March 1979 issue of the journal.

Section editors' addresses are as follows: ATTITUDES AND SOCIAL COGNITION, Melvin Manis, Editor, Research Center for Group Dynamics, Institute for Social Research, University of Michigan, Ann Arbor, Michigan 48106; INTERPERSONAL RELATIONS AND GROUP PROCESSES, Ivan D. Steiner, Editor, Department of Psychology, University of Massachusetts, Amherst, Massachusetts 01003; PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES, Robert Hogan, Editor, Johns Hopkins University, Department of Psychology, 33rd and Charles Streets, Baltimore, Maryland 21218.

When Practice Makes Imperfect: Debilitating Effects of Overlearning

Ellen J. Langer and Lois G. Imber
Harvard University

It was hypothesized that as overlearning leads to "mindlessness," the individual components of a task become relatively inaccessible to consciousness and therefore unavailable to serve as evidence of task competence. This may lead to a decrement in performance if circumstances, for example, a label connoting relative inferiority, lead one to question one's ability. This was tested in the first experiment by varying practice on a task (no practice, moderate practice, and overpractice) by label assigned to subjects (no label, assistant, boss). As predicted, performance decrements resulted for the no practice and overpracticed subjects who were assigned the inferior status label but not for the moderate practice subjects for whom the task components were still salient. In a second experiment it was found that the debilitation could be prevented for an overlearned task by making components of the task salient. Implications for the vulnerability of experts to these performance debilitations are explored.

In a recent article (Langer & Benevento, 1978) it was argued that decrements in performance may result from negative interpersonal contextual factors, like labels that connote inferiority relative to another person (e.g., assistant vs. boss), regardless of the outcome one experiences. It was suggested that, if salient, the inferior label may lead the individual to an erroneous inference of incompetence, resulting in performance decrements.[1] This effect was termed self-induced dependence. It is self-induced in that individuals who are given low status labels relative to other people, for example, may draw unnecessary inferences from those labels that they then generalize to new situations without any external inducement to do so. Self-induced dependence was originally proposed in contrast to learned helplessness (see Seligman, 1975) where a perception of incompetence is clearly externally induced through prior exposure to uncontrollable aversive outcomes.

If people become dependent on labels when performing tasks with which they have had a good deal of prior experience, as was the case in the Langer and Benevento studies, one might assume that they would be even more vulnerable with respect to tasks with which they have had little practice. However, recent research on the "mindlessness of ostensibly thoughtful action" (Langer, 1978, 1979; Langer, Blank, & Chanowitz, 1978; Langer & Newman, 1979) suggests that the reverse may occur. That is, repeated experience with a task actually may *increase* an individual's vulnerability to an experience such as being provided with a label that connotes inferiority.

This research was supported by a grant from the William F. Milton Fund of Harvard University and by Grant MH32946-01 from the National Institute of Mental Health to the first author.

The authors are grateful to Herb Kelman and Ross Rizley for their helpful comments and to Rob Rubin, Marty Richardson, Howard Botwinick, and Paul Levitt for their help in conducting the studies.

Requests for reprints should be sent to Ellen Langer, Department of Psychology, Harvard University, Cambridge, Massachusetts 02138.

[1] Other interpersonal factors that are hypothesized to result in unnecessary performance decrements include no longer performing tasks that others continue to perform, engaging in a demeaning task, or simply allowing someone else to help you.

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3711-2014$00.75

When an individual first approaches a task he/she is necessarily attentive to the particulars of the task. With each repetition of the task, less and less attention to those particulars is required for successful completion of that task. As "mindlessness" is achieved, the components of the task may drop out or coalesce to form a whole. Learning, then, in a sense is learning what elements of the task may be ignored (see Langer, 1978). Repeated practice with the task as a whole rather than with the individual parts may lead to a strange turn of events. The person who has overlearned the task, the expert, may be in a position of knowing that he/she can perform the task, without any longer knowing *how* he or she performs it, that is, without knowing the steps or components that make up the performance. If external factors like labels then led the individual to question his or her competence on these overlearned tasks, the individual would have difficulty supplying information about the solution process as evidence of competence and could erroneously infer incompetence.

The present research was designed to assess this relationship between amount of task experience and vulnerability to an inferior label.

In Phase 1 of the paradigm used, baseline measures are taken as pairs of subjects individually perform a task successfully. In Phase 2 subjects perform a different task together, with one in the role of a "worker" and the other as the "boss." In Phase 3, subjects return to the original task. To test the relationship between vulnerability to external factors like labels and amount of task experience, task experience was also varied in the present investigation. In Phase 1 subjects either were given an opportunity to overlearn a novel task or were given only a moderate amount of practice with that task. In Phase 2, a no practice group was introduced, and all subjects performed a second task under one of three labeling conditions (assistant, boss, no label). In Phase 3 all subjects returned to the original task. A curvilinear relationship between the amount of practice and susceptibility to labels connoting relative inferiority was predicted. Since the vulnerability is presumed to be a function of people losing sight of the intervening steps of the task, it was expected that individuals who had no prior task experience and those for whom the task had become overlearned would show the performance decrement in the inferior label conditions. However, it was predicted that since moderate practice groups would be necessarily attentive to the components of the target task, they would not show the decrement.

Experiment 1

The first study employed a 3×3 design where the variables of interest were label (no label, assistant, boss) and amount of practice (no practice, moderate practice, overpractice).

Method

Subjects. One hundred twenty-six adults were recruited from Boston and New York airport lounges to participate in a study concerned with developing methods to improve task performance. Since there were far more women at the airports than men, either waiting for their own planes or for the departures or arrivals of friends and relatives, we recruited only females.[2] They were informed that for our research we needed people to perform different tasks for us, individually and in pairs. Once 1 subject agreed to participate in the study, a 2nd subject, a stranger to the first, was recruited to be her partner. Thus all subjects were run in pairs, and there were 14 subjects per cell. The experiment was conducted by one female and five male experimenters. Experimenters who administered the tasks were blind to the label assignment.

Task. A novel task was employed so that both extremes of task experience, no practice and overpractice, could be compared. It was also necessary for the task to have several parts so that it could be determined whether, as predicted, overpractice results in obfuscation of the task components. To this end a coding task was devised that involves translating English sentences into a different language where every letter is represented by a corresponding symbol and number. Letters were alphabetically arranged in groups (two groups of nine and one of eight letters); each group had a different symbol (a triangle, circle, or square), and each letter in each group had a number from one to nine (eight). (Punctuation marks had only symbols, rather than symbols and numbers). For example, the letter A

[2] Although the subjects in these studies were all females, there is no reason to assume that the results would not generalize to males. Further investigation is required before this can be determined conclusively, however.

had as the corresponding symbol a triangle and the number 1, and the letter J had as the symbol a circle and the number 1. Subjects were given computer cards on which sentences had been typed, and they were required to transcribe these sentences into the new language. They were to write the symbol below each letter and circle the corresponding number in the column for each letter of the sentence. This task permits subjects to chunk the various elements into fewer and fewer units, thereby facilitating overlearning with repeated practice.

For practical purposes it was important to determine a criterion for overpractice in advance. To that end, the task was pretested on 18 adult female subjects. Subjects were instructed to inform us when they felt as though they could perform the task automatically. After coding two sentences, none of the subjects had overlearned the task. After coding six sentences all subjects were performing the task at least 50% more quickly and more accurately than they had done originally: they no longer referred to the coding reference sheet, their performance reached an asymptote, and by this time they had all reported that the task had become automatic. Therefore, the overpracticed group in the present experiment was given six practice sentences, whereas the moderate practice group was given only two.

Procedure. In Phase 1 of the study subject pairs were randomly divided into three groups: no practice, moderate practice, and overpractice on the coding task. After the task was explained and demonstrated, the overpracticed group was instructed to code six sentences, the moderate practice group was instructed to code two sentences, and the no practice group did no coding. This group went immediately to Phase 2 of the study. Each sentence appeared on a separate computer card. While one experimenter administered this task, a second experimenter, who was hidden from view, recorded the amount of time it took subjects to complete the first sentence. The amount of time it took to complete this sentence and the number of errors made were used as baseline measures for the moderate and overpractice groups.

All subjects now participated in Phase 2 of the research. They were each told that the task they would be asked to perform next required a joint effort: One of them would be the assistant and one the boss (one-third of the pairs performed this task without labels indicating relative status). Subjects were asked to examine a picture and find objects that were hidden in it. One person was to find the objects, and the other was to record the objects found. To control for task effects, for half of the pairs the boss did the searching and the assistant the recording, whereas for the remaining half the tasks were reversed. The experimenter handed subjects the envelope with instructions to place the task materials back in the envelope when they had finished. At that time she/he would return to give them further instructions. In the meantime she/he was purportedly going to recruit two more subjects. Subjects chose a slip of paper from the envelope that indicated both whether they would be in the boss, assistant, or no label condition and what their task would be. When the second experimenter, whose presence was unknown to the subject, observed that the task had been completed she/he signaled the first experimenter, who then returned to complete the final phase of the experiment and thus was blind to the labeling condition.

Table 1
Mean Number of Minutes to Complete the Postlabel Coding Task

Condition	Label		
	Assistant	No label	Boss
No practice	7.10_a	5.50_b	5.40_b
Moderate practice	4.50_b	4.54_b	4.72_b
Overpractice	4.40_b	3.28_c	3.10_c

Note. All cell ns = 14. Cells bearing different subscripts are significantly different from each other: subscript a differs from all other cells at $p < .001$, and subscript c differs from b cells at $p < .05$.

In the last phase of the study, subjects were told that an individual effort rather than a joint effort again was required. All subjects then were asked to code another sentence. (This, of course, was the first sentence for the no practice group.) Once again the second experimenter timed their performance. Both speed and accuracy served as dependent measures.

At the end of the task, all subjects were asked to complete a brief questionnaire. They were asked to make a list of the components of the task. Specifically, subjects were told, "To do the coding task, certain steps were involved. For instance, you had to look at the letter to be coded. Please list as many steps as you can think of which you used to perform the coding task." When subjects completed this questionnaire, they were completely debriefed.

Results and Discussion

Before examining the effects of the label, it is important to verify group comparability at the start of the experiment. Therefore scores for all of the groups that performed the prelabel task were compared. As expected, the analysis of variance of prelabel scores (the amount of time it took subjects to code the first sentence and the number of errors they made) showed no differences among the six groups for which this measure was relevant: the no label, assistant, and boss, moderate practice and overpracticed groups. Speed scores ranged from 5.56 to 5.89, and accuracy scores ranged from 2.36 to 3.07.

It was expected, however, that differences would emerge on postlabel measures. A 3 (No Label, Assistant, Boss) × 3 (No Practice, Moderate Practice, Overpractice) analysis of variance was performed on both the speed and accuracy of the postlabel coding task. The analysis performed on speed scores yielded highly significant main effects for practice, $F(2, 117) = 133.82$, $p < .001$, and label, $F(2, 117) = 25.05$, $p < .001$, as well as a highly significant interaction, $F(4, 117) = 3.96$, $p < .001$.[3] Table 1 presents the mean number of minutes it took to complete the postlabel coding task for each group. A Newman–Keuls test was performed to understand better the relationships among these means and thus the nature of these significant effects. Cells bearing different subscripts in the table are significantly different from each other by this test. As may be gleaned from the table, subjects in the no practice/assistant condition took longer to complete the postlabeling task than did subjects in all other conditions ($p < .001$), whereas subjects in the no label/overpracticed and boss/overpracticed group performed most quickly ($p < .05$). It is, of course, not surprising that subjects who have had enough practice to overlearn a task perform that task faster than subjects do who have had very little practice. What is interesting is the comparison of the assistant and the no label groups within each practice condition. As predicted, the label *assistant* had a detrimental effect for both the no practice and the overpracticed groups but had no effect on the moderate practice condition.

The analysis performed on the number of errors made by subjects on this task yielded very similar results. The analysis yielded highly significant main effects for practice, $F(2, 117) = 12.02$, $p < .001$, and for label, $F(2, 117) = 35.85$, $p < .001$, and a highly significant interaction, $F(4, 117) = 9.80$, $p < .001$. The mean number of errors made by each group is shown in Table 2. A Newman–Keuls test revealed that the means that bear different subscripts in the table are significantly different from each other. Once again, in contrast to the moderate practice group, the label assistant seems to have had a detrimental effect for both the no practice and overpracticed groups. Subjects in both of these groups made at least twice as many errors as subjects in the other conditions did. Although 86% of the overpracticed/assistant group showed a decrement in performance from Phase 1 to Phase 3, only from 7% to 14% of the remaining relevant groups performed more poorly, $\chi^2(2) = 6.08$, $p < .05$.

Table 2
Mean Number of Errors Made in Postlabel Coding Task

Condition	Label		
	Assistant	No label	Boss
No practice	5.35_a	2.36_c	2.00_c
Moderate practice	1.64_c	1.93_c	1.50_c
Overpractice	4.93_b	1.07_c	1.14_c

Note. The cell bearing subscript a differs from those bearing subscript c at $p < .001$. Cell b differs from cells c at $p < .01$. Cells a and b do not differ from each other.

Although decrements were expected on the target task, subjects in the assistant groups should not show a decrement in performance on the intervening hidden objects task because this task has been defined as one that is consistent with their label, that is, it is an "assistant" task. The analysis of these scores in fact revealed no group differences. This further suggests that the assistant subjects took the task as seriously as the other groups of subjects did (see Langer & Benevento, 1978).

Although subjects in all assistant groups apparently took the label seriously, only those who had no prior experience with the target task and those who were overpracticed on it were debilitated by the inferior status label. It was hypothesized and indeed found that this label would not adversely affect subjects in the moderate practice group. This group was expected to be protected from the potentially debilitating effects of the label

[3] Because subjects were run in pairs, there may be a loss of degrees of freedom. A more conservative test that uses the degrees of freedom based on the number of pairs within groups shows that each of the *F*s in this study are still significant at the $p < .001$ level.

because their experience with the task, in contrast to that of the no practice group, has taught them the components of the task, but not so much as to obscure them, in contrast to the overpracticed group. After performing the last task, subjects in each group were asked to list all the components or steps they could think of that were involved in performing the coding task. The mean number of steps listed for the no practice and overpracticed groups ranged from 3.07 to 4.43, whereas the means for the moderate practice groups ranged from 6.07 to 6.21. The analysis of variance revealed a significant main effect for the amount of practice, $F(2, 117) = 30.95$, $p < .001$. A Newman–Keuls test confirmed the prediction: The moderate practice groups listed significantly more steps than either the no practice or overpractice groups, which were not different from each other.

If the components of a task do indeed become obscured with practice, this should be revealed not only in the number of steps listed but also in their degree of specificity. To assess this, each subject's list was rated by two blind raters ($r = .92$) on a 10-point scale that ranged from very specific to very global. The analysis revealed a significant group difference, $F(2, 123) = 31.38$; $p < .001$. A Newman–Keuls test showed that the responses of the no practice group ($M = 7.5$) were equivalent in specificity to the overpracticed group ($M = 6.57$) and that both were far more global than the moderate practice group ($M = 3.6$). Typical steps listed by the no practice and overpracticed groups were "Look at the letter and write in the code." In contrast, typical steps listed by the moderate practice group included such things as "Fill in the circle if it is a capital and check for punctuation." Of course, the more specific one is, the more steps are available to be listed. Therefore, although both measures are interesting, they should not be viewed as independent of one another.

The performance decrements found in this study occur for tasks for which the components are not salient (a novel task and an overlearned task), after the individual had experience in an inferior status position. Therefore one may ask whether these decrements can be prevented by making components of the task salient. The next study was undertaken with this in mind.

Experiment 2

This experiment used basically the same paradigm as that described in Experiment 1. Subjects in Phase 1 performed a task successfully, in Phase 2 they performed a different task in one of three label conditions (assistant, no label, boss), and in Phase 3 they returned to the original task. In this experiment, however, only one level of practice was used. A task was selected that subjects, in all likelihood, already performed automatically. To see whether the debilitation could be prevented by making components of the task salient, task components were listed for half of the subjects before they began Phase 1 of the experiment. Thus the study utilized a 2 (Components Salient/Nonsalient) × 3 (Assistant, No Label, Boss) design. It was predicted that relative to the no label condition, the assistant condition would show a decrement in performance, and the boss condition would either show an increment in performance (as in the Langer & Benevento, 1978, study) or would be equivalent to the no label group (as in Experiment 1 reported in this paper). It was predicted, however, that the performance decrement would occur only in the components-nonsalient condition. That is, it was expected that the salience manipulation would prevent the debilitation, since these subjects now would have a set of task components recently used and verified to supply as evidence if they questioned their ability.

Method

Subjects. Seventy-two adult females were recruited to serve as subjects from the lounges of Logan Airport in Boston. They were asked to participate in a study on developing educational methods where subjects would be asked to perform different tasks either individually or with another person. Once one subject agreed to participate, a second person, who was a stranger to her, was recruited to be her partner. Thus, as in Experiment 1, subjects were run in pairs.

Task. The target task was a proofreading task. This was selected because it is a task that almost

ll literate people have performed—for example, hen reading one's term paper for school, in eading over a letter before sending it, and so orth—and because it is a task where many rules nay be employed without the individual's neces- arily knowing what they are. That is, the indi- idual can locate errors without being able to rticulate why the error is an error. Two articles ere chosen from popular women's magazines for his task. Their titles accurately reflect their con- ent: One was entitled "Is your doctor overcharging ou?" and the other was "Energy savers' guide." The articles were edited so that each contained 40 rrors distributed evenly throughout each article. There were 13 spelling errors, 9 errors of capitaliza- ion, 12 punctuation errors, and 6 grammatical er- ors in each article.

Procedure. All subjects were initially told that one task found helpful for developing educational methods is proofreading.

> Virtually everyone has done this task although they do not necessarily call it proofreading. For example, if you ever read over a paper for school before handing it in, you were proofreading. Or if you ever read over a letter you wrote before sending it to see if it said what you intended it to say, you were proofreading. Therefore we would like you to proofread a story for us.

Components-salient condition: For this condition the experimenter went on to say,

> Most people can do this task even though they are not aware of just how they do it. That is, they are not always aware of the rules they are using. For instance, if you knew the word "susan" should be typed "Susan," you would be using the rule that the first letter of proper nouns is always capitalized. We would like you to make a list of *at least* three things which you would need to know in order to correct a story for errors.

After subjects completed their lists, they were told that we would like them to remember these rules when they read the story we were about to give them to proofread.

> When you find an error, try to recall the rule you used, and then circle the error. You are only given 3 minutes to read the story, so do not expect to finish it. Most people who do this task can find six errors in 3 minutes. If you are able to do this, you should consider yourself successful at this task.

The time allotted for this task was intentionally brief in order to prevent overlearning of the components.

Components-nonsalient condition: Subjects in this condition were also told that proofreading is a task that most people can do. In addition, they were told,

> In order to proofread a story for errors, you should at least glance at each word in the story to see if it is correctly written. For instance, if the word "susan" appeared, you would know it is an error because the word should read "Susan." First, we would like you to make a list of at least three ways in which proofreading is used. We would like you to read this story and circle any errors that you find. You are only given 3 minutes to read the story, so do not expect to finish it. Most people who do this task can find six errors in 3 minutes. If you are able to do this, you should consider yourself successful at this task.

Thus both groups were led to expect success on the task. Instructions encouraged both to pay attention to the story, both were given an example of an error, and both were asked to make task-relevant lists. The difference was that rules for determining errors were generated only by the components-salient group. The task was pretested on a similar group of subjects to ensure that all experimental subjects would be successful at the task, that is, that each subject would find at least six of the errors.

After subjects successfully completed this task, they were told that the second task required a joint effort. One person was to solve a cryptogram task while the other person used the stopwatch provided to keep track of the solution times. The cryptogram task consisted of four lists of five words each that were written in number form. Each number had a corresponding letter (A = 1, B = 2, and so on). The subjects' task was to transcribe the numbers into their alphabet equivalents with the use of a code. Two-thirds of the subject pairs from each of the two conditions described above were told that the task thus "required" someone to be the boss and someone to be the assistant. One-third of the subject pairs performed this task without reference to relative status (no label condition). Task effects were controlled for by varying the label assigned to the particular task (timing vs. solving). That is, for example, for half of the bosses the task was solving and for half the task was timing. After one subject in each pair had been asked to indicate the task she wanted to perform, the pair was informed which task was the boss task and which was the assistant task. Subjects worked together on the cryptogram task for approximately 5 minutes and then were informed that their joint participation was concluded. All subjects then were asked to proofread another story. As in Phase 1 of the study, they were given 3 minutes to locate as many errors in the story as they could. These scores, in comparison with the prelabel proofreading scores, comprised the primary dependent measure.

At the end of the proofreading task, subjects were asked to complete a brief questionnaire. They were asked to make a list of the components of the

Table 3
Mean Number of Postlabel Proofreading Errors Correctly Located

Condition	Label		
	Assistant	No label	Boss
Components salient	14.33_a	13.99_a	14.41_a
Components nonsalient	8.92_b	13.00_a	17.42_c

Note. All cell *n*s = 12. Cells bearing different subscripts are significantly different from each other: subscript b differs from all other cells at $p < .005$, and subscript c differs from all a cells at $p < .05$.

proofreading task. Specifically, subjects were asked to "make a list of rules that you know about writing which helped you to identify errors in the stories." The time it took each subject to make the list was recorded. When subjects had completed the questionnaire, they were completely debriefed.

Results

An analysis of the prelabel scores revealed no difference among the groups. Thus there was group comparability at the start of the experiment. Although the prelabel scores were equivalent across the groups (ranging from 13.33 errors found to 14.67), a very different picture emerges when one examines the postlabel scores. Table 3 shows the mean number of proofreading errors located by each of the six experimental groups. The analysis of these scores yielded a highly significant main effect for label, $F(2, 66) = 8.09$, $p < .001$, and a highly significant interaction, $F(2, 66) = 7.74$, $p < .001$.[4] A Duncan test was computed to reveal the nature of this interaction. As may be ascertained from the subscripts in the table, the major hypothesis of the study was supported. The components-nonsalient group replicated the Langer and Benevento (1978) finding such that, relative to the no label condition, the assistant group showed a severe decrement in performance, whereas the boss group showed a facilitation effect. However, the salience manipulation was successful in wiping out the differences among the groups. The scores for the components-salient condition are virtually identical to the prelabel scores. The correlation for the components-salient groups between their performance on the prelabel and postlabel stories was .83. Similarly, the correlation between prelabel and postlabel stories for the nonlabeled subjects in the components-nonsalient group was .95. Although these groups found as many errors in the second story as in the first, the assistants in the components-nonsalient group found on the average 5.75 *fewer* errors in the second story. The bosses in this group found 2.67 *more* errors on the average than they had in the prelabel story.

Of those subjects in the components-nonsalient/assistant group, 92% showed a decrement from Phase 1 to Phase 3. In contrast to this only 25%–33% of the remaining groups showed a decrement in performance. Both 2×2 comparisons are significant [salient/nonsalient by assistant/boss: $\chi^2(1) = 4.48$, $p < .05$; salient/nonsalient by assistant/no label: $\chi^2(1) = 3.89$, $p < .05$].

To test again that subjects who were labeled *assistant* took the task in Phase 2 seriously, scores for the intervening cryptogram task were compared. As predicted, there were no differences among the groups. Assistants solved the puzzles as quickly as the remaining groups. (Solution times ranged from 43.18 sec to 47.37 sec).

Further evidence that the salience manipulation was responsible for restoring subjects to their prelabel performance comes from the number of rules subjects reported using in the proofreading task and the time it took them to compose this list. Subjects in the salience condition, if they were keeping the rules in mind while performing the task as instructed, should have been able to list more rules more quickly than the components-nonsalient group could. The analysis of the number of components listed (salient $M = 3.56$ vs. nonsalient $M = 2.78$, $t = 2.98$, $p < .005$) and the analysis of time to compose these lists (salient $M = 44.56$ vs. nonsalient $M = 73.81$, $t = 6.39$, $p < .001$) suggest that this was the case.

One might argue that subjects' ability to generate components of the activity both

[4] An analysis using the degrees of freedom based on the number of pairs within groups shows that this more conservative test lowers the p value for these measures to .01.

Table 4
Between-Subjects Correlation Coefficients for Rules Listed at End of Experiment (Yes/No) by Proportion of Errors Found

Type of rule	Errors found/total errors 1	2	3	4
Components-salient condition				
1. Spelling	.69* (.72)	−.40 (.08)	−.20 (−.08)	.22 (.15)
2. Capitalization	−.30 (.01)	.68* (.60)	−.01 (.15)	−.40 (−.32)
3. Punctuation	.00 (.14)	−.01 (−.10)	.67* (.70)	−.46 (−.49)
4. Grammar	.37 (.34)	−.05 (−.18)	−.34 (−.26)	.82* (.63)
Components-nonsalient condition				
1. Spelling	−.35	.07	−.13	.01
2. Capitalization	.09	−.13	.04	.14
3. Punctuation	−.05	.10	−.16	−.14
4. Grammar	.34	.13	.21	−.25

Note. All cell *n*s = 36. Numbers in parentheses represent correlations between rules listed at the start of the experiment by proportion of errors found.
* $p < .001$.

before and after the task suggests that counter to the position presented here, the components are not inaccessible. However, although subjects in the components-nonsalient condition listed rules after the task, that does not mean that they used those rules (i.e., identified errors as a function of realizing why they were errors) while performing the proofreading task (see Dweck & Gilliard, 1975). In fact, it is important to demonstrate that they did *not* use the rules, whereas the components-salient group *did*. To do this, the next analysis was conducted to see the relationship between the ability to list certain rules and the actual use of those rules. Since all subjects made a list at the end of the last proofreading task, this list was used for the first comparison. Table 4 shows the correlation coefficients for the type of rule listed by the proportion of errors found for each type of error. Correlation coefficients bearing asterisks are significant at $p < .001$. As may be seen in the table by looking at the diagonals, the relationship between listing and finding particular errors was significant for the components-salient group, but there was no such relationship for the components-nonsalient group. That is, for example, subjects who listed spelling found more spelling errors than subjects who did not list spelling in the components-salient condition, and this was not the case for the components-nonsalient group.

As may be seen in the top portion of Table 4, the correlations between rules listed at the beginning of the experiment and the proportion of errors found (these correlations are reported in parentheses in the table) are also significant at $p < .001$. This strongly suggests that the salience manipulation was effective in providing subjects with rules to use while they performed the proofreading task.

To explore further the relationship between rules listed and errors found, a second correlational analysis was performed on *within*-subjects scores. This analysis yielded a coefficient that represented, for every subject, the relationship between rules listed and the proportion of errors of each type that were found. These correlation coefficients were then transformed into Z scores, and the resulting analysis yielded a significant effect for salience, $F(1, 66) = 71.12$, $p < .001$. The mean correlations between the types of rules listed and the types of errors found ranged from −.29 to −.01 for the components-nonsalient conditions and from .77 to .86 for the components-salient groups. Clearly there was a strong relationship between rules listed and the rules

used for the components-salient group that was absent for the components-nonsalient group.

Discussion

Both experiments provide strong support for the assumption that overlearning may lead to increased vulnerability to labels that connote relative inferiority. In the paradigm used, the effect of the label reveals itself in the final phase of the experiments. Subjects in the second phase of both studies are performing what is deemed by the label *assistant* to be a low status task. There is no reason, therefore, for them to question their ability to perform it. However, the original and final tasks are not assistant tasks. To the extent that subjects accept the validity of the label, they may question their competence with regard to tasks that may now be perceived as psychologically inconsistent with that label. Such questioning will not necessarily have negative consequences, if the individual can convince himself or herself that he or she in fact can perform the task. This evidence must be lacking with respect to a novel or unfamiliar task. If, as the present studies suggest, overlearning results in the obfuscation of the individual components of the task, evidence also will be lacking in this case. Therefore only groups with moderate experience should be able to proceed with the task unhampered by the label. Experiment 1 showed this to be true. Performance decrements resulted after the label assignment for the no practice and the overpracticed groups but not for the moderate practice groups.

Since the overpracticed group was able to generate task components when asked to do so, it is important to consider why this information did not protect them from the label's influence. The present research suggests two reasons for this. First, the overpracticed subjects did not list very specific task components. One might reasonably assume that global knowledge of what a task consists of should not be very confidence inducing. If one wanted to teach the task to someone else, for example, these global components alone would be inadequate. Second, the untreated overpracticed group in Experiment 2 showed no relationship between the steps generated and the steps they actually used in performing the task. Being able to list components that *could* possibly be used to complete a task should not be as confidence inducing as knowing steps that *were* experienced successfully.

The second experiment provides evidence that the decrement in performance that may occur on overlearned tasks may be prevented. It will be recalled that this experiment compared two overpracticed groups: a group that, except for the tasks used, basically was treated just as the overpracticed group in the first experiment had been and a second group for whom the components of the task were made salient. The performance decrement occurred again for subjects bearing the inferior label in the untreated group. Making the components of the task salient, however, apparently inoculated the comparison group of subjects against the potential effects of the label.

One may question how the salience manipulation in Experiment 2 could have been effective in light of the assumption, for which all of us can summon anecdotal support, that renewed attention to that which is overlearned is disruptive (cf. Kimble & Perlmutter, 1970; Langer, 1978). The salience manipulation made subjects attend to an overlearned task, yet their performance was not hampered. The reason for this is likely to lie in the fact that subjects were asked to generate steps necessary to perform the task *before* performing it. Subjects in the components-salient group showed a strong relationship between the components they generated initially and the components they attended to while performing the task, whereas subjects in the group left to their own devices (the components-nonsalient group) showed no relationship between the components they generated afterward and the components they attended to while performing the task. This suggests that the salience manipulation led subjects in some sense to follow a new set of rules for themselves. Therefore, if they were approaching the task with a new set of rules (thereby changing the task to a nonoverlearned task), attention to those rules (which was revealed in the high correlation

etween the rules cited and the ones actually sed) should not be disruptive. And of course erformance on an overlearned task also ould not be disrupted if it simply were per-ormed automatically without bringing com-etence into question. The proficiency mani-ested by subjects in the overpracticed/no abel and boss groups in Experiment 1 bears his out. Thus although negative external actors like pejorative labels may be quite ebilitating, they, of course, are not neces-arily so. What about positive external fac-ors? The data from the present studies do ot permit any clear conclusions with respect o the label "boss." More research on situa-ional and individual difference variables is ecessary before any conclusions about posi-ive labels can be drawn.[5]

In addition to exploring the potentially acilitating effects of positive external influ-nces like labels, additional research is also equired to understand more fully the rela-ionship between particular task character-stics and performance debilitation of this ort. The present analysis would suggest that asks that have only one step, tasks whose erformance requires the articulation of steps (e.g., learning the alphabet), or tasks that are so complex as to preclude complete mas-tery would not render the individual vulnera-ble to external influences. Vulnerability may be evident for many, if not most, other tasks, however.

It is clear that overlearning is adaptive, since it frees limited attention to be paid elsewhere. It would seem from their daily interactions that most people in the world are aware that overlearning serves this function, since they appear to be constantly adding familiarity, predictability, and structure to their lives, which facilitate overlearning. While acknowledging the adaptive function mindlessness or overlearning may serve in freeing limited capacity, the present article supports previous work (Langer, 1978, 1979; Langer, Blank, & Chanowitz, 1978; Langer & Newman, 1979; Langer, Note 1; Langer & Weinman, Note 2) in demonstrating the ways in which mindlessness may also be mal-adaptive.

Although the detrimental effects of over-learning may be pervasive, it is also likely that some subject populations are more susceptible to these effects than others are. For example, the elderly are a group who for many reasons (see Langer, 1978, 1979, Note 1) probably have more experience with overlearned tasks than the nonelderly do. Children probably have more experience with no practice tasks relative to nonchildren. Thus these two groups should be most susceptible to external factors, such as pejorative labels, that may lead one to question one's competence. Although the groups may look similar, they are of course quite different in that the elderly can in fact do the tasks in question. Similarly, people who chronically occupy low status jobs are likely to be particularly susceptible. However, most interesting, perhaps, would be the inclusion of experts on this list.

Although one probably does not want to discourage overlearning or the attainment of mindlessness because of its general advantage in fast and efficient performance, educating people as to the potential side effects would seem fruitful. However, the present research suggests another, more direct way in which potential performance decrements may be prevented. Stated generally, focusing on process

---

[5] In the original Langer and Benevento studies, the label "boss" had a facilitating effect such that relative to the no label conditions, these groups performed significantly better. Although this was also true for Experiment 2 in the present investigation, it was not true for the first experiment. Here subjects labeled *boss* within each level of practice were equivalent to the no label groups. The fact that the "boss" group across all four studies did not show a decrement in performance suggests that the majority of subjects in this condition are not questioning their ability to perform the task, for such questioning for the overlearned and no practice groups would reveal to them an inability to find evidence to support the label. If one goes back to the original studies (Langer & Benevento, 1978), one finds that whereas the boss groups on the average performed better than the no label groups, the proportion of subjects who performed this way is the same for both groups. Although most subjects are unquestioningly accepting the label and trying to live up to it, it would appear that a few are not so accepting. The relative proportions from experiment to experiment of this latter minority group would determine whether the aggregate measures reveal equivalence, facilitation, or perhaps even debilitation.

rather than on outcome may reduce vulnerability to debilitation of this kind.

Idiosyncratic Weighting of Trait Information in Impression Formation

Thomas M. Ostrom
Ohio State University

Deborah Davis
University of Nevada, Reno

An analysis is offered of the role of unequal weighting in the averaging model of information integration. A distinction is made between unequal weighting at the normative level (which has been referred to as "differential weighting") and unequal weighting at the level of the individual subject (which we refer to as "idiosyncratic weighting"). Two studies are reported that examine the prevalence of idiosyncratic weighting in the trait-judgment impression formation task. Whereas most past research on the question of unequal weighting in this task involved averaging responses across both subjects and stimulus replications, the present studies were analyzed at the level of an individual subject's repeated responses to separate stimulus replications. Clear evidence of idiosyncratic weighting was obtained from about 50% of the 120 subjects; only 20% of the subjects indicated absolutely no tendency toward unequal weighting. There was no evidence that idiosyncratic weighting was restricted to just a subset of stimuli, since all of the 20 stimulus replications showed idiosyncratic weighting effects. In contrast to previous findings, negative traits did not always receive more weight than positive traits. In more than 20% of the instances of unequal weighting, the more positive trait was accorded a higher weight.

Information integration theory (Anderson, 1974) offers an approach for understanding how people combine stimulus information when making judgments and decisions. The theory seeks to determine the nature of the integration rule (e.g., adding, averaging, multiplying) employed by people in various response domains. In addition, it provides a way to determine whether all stimulus items in the domain contribute equally to the overall judgment or whether they carry different weights.

Integration theory provides no a priori basis for predicting which integration rule or weighting assumption is correct for any particular response domain. It does, however, provide an array of conceptual alternatives along with a diagnostic methodology (functional measurement). With a comprehensive series of studies, it is possible to determine which conceptual alternatives best describe a response domain. Hence, one of the great strengths of integration theory is its ability to uncover different integration rules for different response domains.

In order to apply integration theory to a response domain, it is necessary to specify two features of that domain, the population of information or stimulus items and the nature of the subjective judgment continuum. It is necessary to specify these two features because a shift in either may affect the integration rule or parameter values. For example, one integration rule may apply when traits are combined with traits (e.g., averaging), and a different rule might apply when traits are combined with adverbs (e.g., multiplication). Parameter values may also vary as the nature of the judgment continuum shifts. Whereas *friendly* may have a higher scale value than

energetic on the favorability continuum, it is likely that *energetic* would have the higher scale value on an activity continuum.

Integration theory has been used extensively to analyze the adjective combination task first introduced by Asch (1946) to study impression formation processes. The stimuli used in the impression formation task are personality trait adjectives, and the response continuum refers to overall impression favorability. At the operational level, most investigators use the 555 traits scaled by Anderson (1968) as their domain of stimuli. The judgment scale usually has seven or more intervals and is anchored with the bipolar terms of favorable–unfavorable or like–dislike.

It is widely assumed that for the impression formation response domain, people employ an averaging integration rule and assign approximately equal weights to all stimuli in the stimulus domain. Anderson has offered this view of an equal weighting model in a number of sources (Anderson, 1974, p. 261; Anderson, 1976, pp. 681–682; Anderson & Lopes, p. 69; Leon, Oden, & Anderson, 1973, pp. 301–302; Oden & Anderson, 1971, p. 159). The main objective of the present article is to examine the assumption that all personality trait adjectives, as items of person information, carry approximately equal weight in the impression formation task.

This assumption of equal weighting has been questioned by some investigators (e.g., Birnbaum, 1974). In the following review of research bearing on the equal weighting question, we note that existing data are not conclusive regarding the source or strength of differences in trait weights. One of the problems with this research is that most of the studies are based on group averages. This paper explores the possibility that such group data may "average out" idiosyncratic differences in trait weights that exist separately for each individual.

Differential Weighting

Two kinds of deviations from equal weighting have been examined in previous research; one is related to the lability of a trait's weight, and the other concerns the variation in weight between different traits.

Weight lability. The lability of a trait's weight reflects the extent to which the weight is affected by situational or contextual variables. There can be little question as to whether "differential" weighting occurs in the impression formation domain in this sense of the term.

Characteristics of the judgment task are known to affect the functional weight given any particular item. For example, communicator credibility (Rosenbaum & Levin, 1968) and serial position (Anderson, 1965) can act as situational determinants of trait weight.

Weight can also be influenced by the semantic relationship that a trait holds with other items in the set. The weight parameter is affected by the level of redundancy (Schmidt, 1969) and inconsistency (Anderson & Jacobson, 1965) among traits describing the same person. Also, there are traits that possess two distinct semantic meanings (polysemous homographs)—traits such as *discriminating* and *sensitive*—that may change their scale value as well as their weight, depending on other stimuli in the information set. Although each of the above features can lead to differential weighting, they all derive from the relationship between the semantic definitions of the different traits and can in principle be specified a priori. They do not represent instances in which particular traits carry different weights when in isolation from one another.

Weight differences between traits. The weights of most, if not all, traits are clearly labile. However, this does not mean that traits differ in their natural or context-free weights. When variables known to influence lability are held constant, it is possible that trait weights are either approximately equal or substantially different from one another. It is this sense of the term *differential weighting* that is being rejected when the integration process in impression formation is said to conform to an equal-weight averaging model.

Several possible determinants of trait weight have been examined. Both trait novelty (Wyer, 1970) and trait ambiguity (Kaplan, 1971, 1975; McKillip, Barrett, & Dimiceli, 1978; Schümer, 1973; Wyer, 1974b; Wyer & Watson, 1969) have received some attention.

In neither case, however, do the findings unequivocally support the conclusion of differential weighting in the integration process.

Other research has been directed toward sources of differential weighting that are associated with trait scale value. It is possible, for example, that traits with extreme scale values carry more weight than do neutral traits (e.g., Warr, 1974; Warr & Jackson, 1975). These findings are difficult to interpret, however, because of confounding between negativity, ambiguity, and extremity (Warr & Jackson, 1976; Wyer, 1973).

Unlike the above potential sources of differential weighting, research findings have unequivocally established the existence of a negativity effect. Traits with a negative valence tend to carry more weight than those with positive valence (e.g., Birnbaum, 1974; Hodges, 1974; Oden & Anderson, 1971). This negativity effect is thought to exist for a number of response domains (Kanouse & Hanson, 1972).

Although the negativity findings represent a genuine limitation to the equal weighting assumption, they may not be especially serious. Anderson (1974, p. 261) has speculated, for example, that the magnitude of this negativity effect is not very large and that it may be restricted to only extremely negative stimuli. Another difficulty with this research is that it only employed a limited sample of positive and negative traits. No attempt was made to see how representative the sample was of the entire trait population. The possibility exists that most traits have equal weights, but that a few negative traits carry a higher weight and a few positive traits a lower weight. One objective of the present research was to examine these questions about the negativity effect.

Idiosyncratic Weighting

Most work on the issue of differential weighting has been at the level of *normative* weights. That is, the research has examined how much weight is given traits by the typical or average subject. Little consideration has been given to the problem of whether or not equal weighting applies to each person individually. It is possible that because of a person's idiosyncratic experiences with different trait adjectives, he or she may assign widely differing weights to the adjectives. However, one person's pattern of weights may be unrelated to another's. One person may weight *friendly* twice as much as *intelligent*, whereas another might give *friendly* only half the weight of *intelligent*. If we were to obtain normative weights by averaging over these two persons (as is the case in most differential weighting research), we would find that the two traits received the same weight. Differential weighting of traits at the level of a single subject (what we term *idiosyncratic weighting*) may emerge as equal weighting when measured at the normative level.

Only one published study has examined the possibility of idiosyncratic differences in trait weights. In this study (Anderson, 1962), the stimulus sets consisted of three traits, one from each of the three factors in the design. Each factor consisited of a negative, neutral, and positive trait to form its three levels. This $3 \times 3 \times 3$ design resulted in a total of 27 stimulus sets. Subjects judged all 27 sets once a day for 5 days. The resulting data were analyzed to determine whether significant interaction variance emerged. This design was repeated for 12 subjects, with every 2 subjects receiving a different stimulus replication (i.e., six stimulus replications of the three-factor design, with 2 subjects per replication). The test for differential weighting (or nonadditivity) was performed on the pooled (i.e., 20 degrees of freedom) interaction. Of the 12 subjects, 3 were found to produce significant nonadditivity.

Even though the total number of subjects was small, this study suggests that about 25% of the people show differential weighting. That percentage figure would, no doubt, have been higher had each of the two-way interactions and the three-way interaction been separately tested for each subject. It would be possible for a subject to have a significant two-way interaction but not to have the pooled interaction reach significance.

On the other hand, it is possible that the 25% figure is actually an overestimate of the number of people displaying differential weighting. Two of the three subjects with sig-

energetic on the favorability continuum, it is likely that *energetic* would have the higher scale value on an activity continuum.

Integration theory has been used extensively to analyze the adjective combination task first introduced by Asch (1946) to study impression formation processes. This assumption of equal weighting has been questioned by some investigators (e.g., Birnbaum, 1974). In the following review of research bearing on the equal weighting question, we note that existing data are not conclusive regarding the source or strength of differences in trait weights. One of the problems with this research is that most of the studies are based on group averages. This paper explores the possibility that such group data may "average out" idiosyncratic differences in trait weights that exist separately for each individual.

Differential Weighting

Two kinds of deviations from equal weighting have been examined in previous research; one is related to the lability of a trait's weight, and the other concerns the variation in weight between different traits.

Weight lability. The lability of a trait's weight reflects the extent to which the weight is affected by situational or contextual variables. There can be little question as to whether "differential" weighting occurs in the impression formation domain in this sense of the term.

Characteristics of the judgment task are known to affect the functional weight given any particular item. For example, communicator credibility (Rosenbaum & Levin, 1968) and serial position (Anderson, 1965) can act as situational determinants of trait weight.

Weight can also be influenced by the semantic relationship that a trait holds with other items in the set. The weight parameter is affected by the level of redundancy (Schmidt, 1969) and inconsistency (Anderson & Jacobson, 1965) among traits describing the same person. Also, there are traits that possess two distinct semantic meanings (polysemous homographs)—traits such as *discriminating* and *sensitive*—that may change their scale value as well as their weight, depending on other stimuli in the information set. Although each of the above features can lead to differential weighting, they all derive from the relationship between the semantic definitions of the different traits and can in principle be specified a priori. They do not represent instances in which particular traits carry different weights when in isolation from one another.

Weight differences between traits. The weights of most, if not all, traits are clearly labile. However, this does not mean that traits differ in their natural or context-free weights. When variables known to influence lability are held constant, it is possible that trait weights are either approximately equal or substantially different from one another. It is this sense of the term *differential weighting* that is being rejected when the integration process in impression formation is said to conform to an equal-weight averaging model.

Several possible determinants of trait weight have been examined. Both trait novelty (Wyer, 1970) and trait ambiguity (Kaplan, 1971, 1975; McKillip, Barrett, & Dimiceli, 1978; Schümer, 1973; Wyer, 1974b; Wyer & Watson, 1969) have received some attention.

In neither case, however, do the findings unequivocally support the conclusion of differential weighting in the integration process.

Other research has been directed toward sources of differential weighting that are associated with trait scale value. It is possible, for example, that traits with extreme scale values carry more weight than do neutral traits (e.g., Warr, 1974; Warr & Jackson, 1975). These findings are difficult to interpret, however, because of confounding between negativity, ambiguity, and extremity (Warr & Jackson, 1976; Wyer, 1973).

Unlike the above potential sources of differential weighting, research findings have unequivocally established the existence of a negativity effect. Traits with a negative valence tend to carry more weight than those with positive valence (e.g., Birnbaum, 1974; Hodges, 1974; Oden & Anderson, 1971). This negativity effect is thought to exist for a number of response domains (Kanouse & Hanson, 1972).

Although the negativity findings represent a genuine limitation to the equal weighting assumption, they may not be especially serious. Anderson (1974, p. 261) has speculated, for example, that the magnitude of this negativity effect is not very large and that it may be restricted to only extremely negative stimuli. Another difficulty with this research is that it only employed a limited sample of positive and negative traits. No attempt was made to see how representative the sample was of the entire trait population. The possibility exists that most traits have equal weights, but that a few negative traits carry a higher weight and a few positive traits a lower weight. One objective of the present research was to examine these questions about the negativity effect.

Idiosyncratic Weighting

Most work on the issue of differential weighting has been at the level of *normative* weights. That is, the research has examined how much weight is given traits by the typical or average subject. Little consideration has been given to the problem of whether or not equal weighting applies to each person individually. It is possible that because of a person's idiosyncratic experiences with different trait adjectives, he or she may assign widely differing weights to the adjectives. However, one person's pattern of weights may be unrelated to another's. One person may weight *friendly* twice as much as *intelligent*, whereas another might give *friendly* only half the weight of *intelligent*. If we were to obtain normative weights by averaging over these two persons (as is the case in most differential weighting research), we would find that the two traits received the same weight. Differential weighting of traits at the level of a single subject (what we term *idiosyncratic weighting*) may emerge as equal weighting when measured at the normative level.

Only one published study has examined the possibility of idiosyncratic differences in trait weights. In this study (Anderson, 1962), the stimulus sets consisted of three traits, one from each of the three factors in the design. Each factor consisited of a negative, neutral, and positive trait to form its three levels. This $3 \times 3 \times 3$ design resulted in a total of 27 stimulus sets. Subjects judged all 27 sets once a day for 5 days. The resulting data were analyzed to determine whether significant interaction variance emerged. This design was repeated for 12 subjects, with every 2 subjects receiving a different stimulus replication (i.e., six stimulus replications of the three-factor design, with 2 subjects per replication). The test for differential weighting (or nonadditivity) was performed on the pooled (i.e., 20 degrees of freedom) interaction. Of the 12 subjects, 3 were found to produce significant nonadditivity.

Even though the total number of subjects was small, this study suggests that about 25% of the people show differential weighting. That percentage figure would, no doubt, have been higher had each of the two-way interactions and the three-way interaction been separately tested for each subject. It would be possible for a subject to have a significant two-way interaction but not to have the pooled interaction reach significance.

On the other hand, it is possible that the 25% figure is actually an overestimate of the number of people displaying differential weighting. Two of the three subjects with sig-

nificant interaction variance received the same stimulus replication. It is conceivable that this particular stimulus replication contained inconsistent traits, redundant traits, or polysemous homographs. Anderson (1962) did not report attempting to avoid stimulus combinations of this sort.

There is a second reason that the 25% figure might be an overestimate. There is no way to verify that the response scale that these three subjects used to make their judgments was linearly related to the underlying subjective continuum. It is possible that these three subjects assigned equal weight to all stimuli but that in reporting their subjective impressions they did not use an equal-interval response scale. For example, a statistical interaction of the form implying that negative traits carry more weight than positive traits could be produced by a nonlinear response scale if the categories at the negative end of the scale were wider (i.e., covered a greater range of the subjective continuum) than the categories at the positive end.

The research in the present paper was undertaken to provide a more thorough test of the prevalence of idiosyncratic weighting in the trait judgment domain. Two studies are reported, both of which have the same methodological features. The studies were designed to maximize the likelihood of detecting idiosyncratic weighting. The design used by Anderson (1962) was improved upon in six ways.

The stimulus sets used by Anderson contained three traits. According to the averaging model, however, the observable effects of weight differences due to a single trait decrease as the number of other traits in the set increases. To maximize sensitivity to differential weighting, the present studies used sets composed of only two traits.

Second, there is a need to increase the number of stimulus replications (Anderson, 1962, used only six). The use of an interaction to test the presence of differential weighting is contingent upon having the two traits with a difference in weight present in the same factor of the design. That is, the two must both be on Factor A or on Factor B. If two highly weighted stimuli are on Factor A and two low weighted stimuli are on Factor B, the averaging model predicts no interaction, and so the effect of the weight differences would go undetected. Increasing the number of stimulus replications increases the likelihood that at least some traits with differential weights will be assigned to the same factor in the design. The present research employed 10 different stimulus replications in the first study and 10 new replications in the second.

Third, most research applying integration theory to the trait-judgment domain has used equal weighting instructions in which subjects are explicitly told that each trait is accurate and equally important and that the subject should pay full attention to each of them. To the extent that subjects actively bear those instructions in mind while making their judgments, it is possible that differential weighting is suppressed in this line of research. Some support for this notion is offered by Anderson and Jacobson (1965), who obtained slightly stronger evidence of inconsistency discounting under naturalistic instructions than under equal weighting instructions. The first study in this paper deleted any mention of equal weighting, and the second study manipulated weighting instructions as a factor.

Fourth, it is possible that the design-wide structure of the stimulus combinations could lead subjects to adopt an equal weighting set regardless of the explicit instructions. Anderson (1962) presented subjects with all 27 combinations in the three-factor design. That meant that each trait appeared nine times, once with every combination of all the traits from the other two factors. Each trait appeared in one third of all the test sets presented. It is possible that such extensive repetition induces a mechanistic judgment set in which the subject actively suppresses any differential weighting that he or she might naturally bring to the task. In the present studies, 40 test sets are presented, and no adjective appears in more than 2 of the 40.

Fifth, if differential weighting applies only to some stimuli and not to others, it is important to design the study so as to maximize the likelihood of identifying those stimulus-subject combinations that display differential weighting. Whereas the basic interaction used

in Anderson (1962) was a 3 × 3 (or four degrees of freedom) interaction, the present study used a 2 × 2 (or one degree of freedom) interaction. In the Anderson design, it would be difficult to detect a significant interaction that was due to only one of the six stimuli entering into a 3 × 3 interaction. Although the effect of differential weighting in that design might affect only one of the four components of the interaction, statistically it would be spread out over the four degrees of freedom and, when tested on that basis, might not produce overall significance. In a 2 × 2 design, however, differential weighting contributed by a single trait would be wholly contained in the one-degree-of-freedom interaction term.

Lastly, the Anderson (1962) study employed only 12 subjects. It is difficult to generalize about an estimate of the percent of people displaying differential weighting from such a small sample. In the present paper, 40 subjects were used in the first study and 80 in the second, providing greater confidence in the generality of the findings.

Experiment 1

In the first experiment, each subject was given 40 two-trait stimulus sets to judge on a likeability scale once a day for five days. The stimulus sets contained 10 replications of a 2 × 2 design in which each factor of the design contained a moderately favorable and a moderately unfavorable trait. Each stimulus replication provided one opportunity for differential weighting to emerge, offering 10 opportunities for each subject. Such a design not only allowed an analysis of the prevalence of idiosyncratic weighting but permitted a determination of whether significant interactions emerge from many or only a few stimulus replications. Further, a qualitative analysis of the pattern of means for significant interactions can reveal the proportion of unequal weight due to negative traits carrying more weight than positive traits.

Method

Subjects

Subjects were 40 introductory psychology students, 19 males and 21 females, at Ohio State University, who participated in partial fulfillment of course requirements.

Stimuli

The stimulus trait adjectives were arbitrarily selected from Edward's (Note 1) Ohio State rescaling of Anderson's (1968) personality trait adjectives. Subjects judged 40 stimulus trait pairs, 4 pairs from each of 10 stimulus set replications. The 4 pairs from each replication represented the four cells of a 2 × 2 factorial design. Each factor of this design had two levels of trait likeableness, a moderately favorable (M+) trait and a moderately unfavorable (M−) trait. For each replication there is one M+M+ trait pair, two M+M− trait pairs, and one M−M− trait pair. Mean scale values for the M+ and M− traits were 5.5 and 2.5, rated on a scale of likeability ranging from 1 (dislike very much) to 7 (like very much). In selecting traits for each replication, care was taken to eliminate all instances of redundancy and inconsistency.

Procedure

When subjects arrived for the first day of the experiment they received the following written instructions:

> This experiment is concerned with impression formation. What we are interested in is how people form impression of others on the basis of very limited information. . . .
>
> In this particular experiment, you will be seeing pairs of traits that describe various persons. You will be asked to tell how much you would like each person. Imagine that each of the two traits was contributed by a different person who knows him (her) well.
>
> Read each pair carefully, try to imagine the type of person being described, and rate how much you like the person, using the scale given below each pair of traits. Sometimes this may seem hard, but just act naturally and do the best you can.

All subjects judged the same 40 stimulus sets on each of 5 successive days. Stimulus sets were presented in a booklet, 1 set to a page. There were five random orders of stimuli. The five booklet orders were Latin square counterbalanced across the 5 days, so that each subject received each booklet order and all booklet orders appeared equally often over the 5 days. Ratings were made on a 21-point scale ranging from 10 (like very much) to −10 (dislike very much).

Results

Group Data

Most studies that have tested for equal weighting in the adjective judgment task have

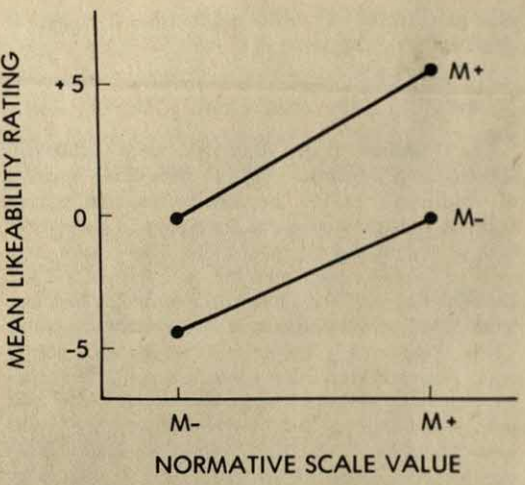

Figure 1. Mean likeability rating of adjective sets composed of M+ and M− (moderately favorable and moderately unfavorable) traits, averaged over days, stimulus replications, and subjects in Experiment 1.

averaged over both stimulus replications and subjects. In analyzing the present group data, the question of equal weighting can be examined both on this overall basis and within each stimulus replication.

If traits are equally weighted, there should be no interaction between the M+ and M− levels of the A factor and the M+ and M− levels of the B factor. The present group data brings considerable power to the test of that interaction; each cell mean is the average of 2,000 ($10 \times 5 \times 40$) observations. The interaction (see Figure 1) was significant, $F(1, 39) = 10.35$, $p < .005$, and its pattern is similar to that obtained by previous investigators. It can be explained by assuming that negative traits carry more weight than positive traits.

Whether the obtained overall interaction represents a serious challenge to the equal weighting assumption is contingent upon several factors, including its magnitude, the proportion of stimulus replications that contribute to it, the presence of similar versus differential interaction patterns across stimulus replications, and whether response scale nonlinearity could account for the significant effects.

The magnitude of the overall interaction was not very substantial. The interaction contributed only one percent to the total between-cells variance. With fewer observations going into each cell mean, this interaction could well have gone undetected.

It is conceivable that the overall interaction was due to only a few of the 10 stimulus replications. In line with Anderson's (1974) suggestions, it could be the result of the one or two stimulus replications that contained the most extremely negative traits from the M− range. There is a second advantage to examining each of the stimulus replications separately. It is possible that the pattern displayed in Figure 1 does not hold for all significant stimulus replications. If the majority of the significant interaction replications showed the pattern in Figure 1 and were averaged with others that showed different patterns (e.g., convergence rather than divergence to the right of the graph), the observed overall interaction could still have emerged.

Separate analyses were performed on each of the 10 stimulus replications, and only 2 were found to contain significant interaction variance, $Fs(1, 1521) > 6.11$, $ps < .05$.[1] The percent of between-cells variance contributed by the interaction was 3.40 and 3.80 for the first and eighth replications, respectively. The solid line portions of Figure 2 display the interactions for those 2 stimulus replications. Both replications showed the same pattern—one that could be explained by assuming that negative traits carry more weight than positive traits do.

A significant interaction could be produced by weight differences between the two traits on the A factor, on the B factor, or on both. Each stimulus replication, then, provides two opportunities for differential weighting to occur. The fact that only two of the replications had significant interactions means that near equal weighting was observed in between 16 and 18 of the 20 opportunities. At this normative level of analysis, it appears that equal weighting was characteristic of 80% to 90% of the trait pairs. The overall negativity effect was produced by at most 20% of the stimulus pairs.

[1] The error term for these analyses was the interaction between subjects (40) and stimulus persons (40).

The data provide some support for the interpretation that differential weighting is restricted to highly negative traits. The lowest marginal mean was computed for each stimulus replication to provide an index of which replications contained the most negative trait. Among the 10 stimulus replications, the 2 replications for which the interaction was significant were the first and fifth lowest.

Response scale linearity. Significant interactions of the form portrayed in Figures 1 and 2 could be obtained even if all traits were subjectively given equal weights. This would occur if subjects used wider categories at the negative end of their response scale than at the positive end. In such a case, subjects' overt responses would not be linearly related to their subjective responses. Two qualitative tests were devised for the purpose of examining the response scale explanation.

Response scale nonlinearity can be dismissed if the qualitative pattern satisfies a *test of disordinality*. The interaction portrayed in Figure 1 is termed an ordinal interaction because both the lower and upper lines are ordinally related to the horizontal axis in the same direction (i.e., the sign of both slopes is the same). A disordinal interaction would be one in which the slope of one line is positive and the slope of the other is negative. If the means of a 2 × 2 design can be plotted so that disordinality emerges, there exists no continuous monotonic transformation of the response scale that will reduce that interaction to zero. Consequently, the presence of disordinality supports an unequal weighting interpretation. Although none of the stimulus replications in the analysis of group data (see Figure 2) displayed such a pattern, it is useful to point out the implications of such a pattern for response scale linearity prior to discussing the individual data.

The *intersection test* involves comparing the data pattern of a significant interaction for one stimulus replication against a base line provided by a nonsignificant (i.e., interaction $F \leq 1$) stimulus replication. If the judgments contributing to both interactions came from comparable portions of the response scale, no continuous monotonic quadratic transformation of the response scale (e.g., using wider

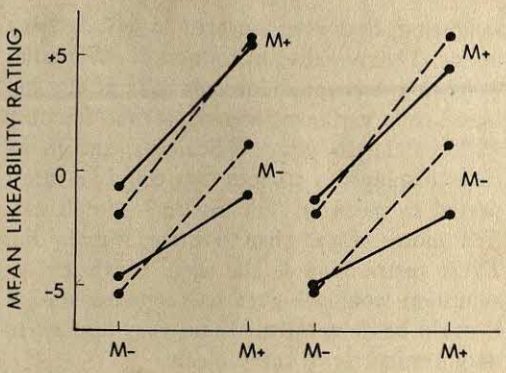

Figure 2. Use of the intersection test to eliminate scale nonlinearity as an explanation of the interactions obtained when averaging over days and subjects in Experiment 1. (M+ = moderately favorable. M− = moderately unfavorable. The significant interactions for Stimulus Replications 1, $F(1, 156) = 6.35$, and 8, $F(1, 156) = 6.12$, are in solid lines and the nonsignificant control interaction from Stimulus Replication 3, $F(1, 156) = 1.00$, is in dashed lines.)

categories at the negative than at the positive end) could simultaneously reduce both interactions to zero. The intersection test provides a way of insuring that both the significant interaction and the nonsignificant control interaction involved responses from similar portions of the rating scale. The control stimulus replication must be selected so that when the two interactions are graphed together, the lower lines of each intersect one another and the upper lines of each intersect one another.

This intersection test was applied to both significant stimulus replications for the group data. It was found that Stimulus Replication 3 ($F = 1.00$), in which the interaction accounted for only 0.43% of the between-cells variance, provided such a control for both significant replications (see Figure 2). It can be concluded, then, that the two significant interactions portrayed in Figure 2 represent genuine instances of unequal weighting and should not be dismissed on the grounds of simple response scale nonlinearity.

Individual Data

The analyses of group data verified the presence of differential weighting in the trait-judgment paradigm. The deviation from equal

weighting, however, appeared to be relatively minor. The overall contribution of differential weighting accounted for only 1% of the between-cells variance, was significant for only 20% of the stimulus replications, and in all cases displayed a pattern that could be interpreted as meaning that negative stimuli carried more weight than positive stimuli did. These restrictions on the equal weighting assumption would be even less consequential if it could be demonstrated that they applied to only a minority of the subjects.

Setting alpha at .05 and testing each 2 × 2 stimulus replication interaction against the subject's own Days (5) × Stimulus Persons (40) interaction (on 156 degrees of freedom), a full 82.5% of the subjects showed evidence of nonadditivity for at least 1 of the 10 stimulus replications (see Table 1).

One difficulty with the use of 10 stimulus replications lay in the increasing role of chance as the number of replications increased. Assuming that 5 subjects out of 100 would produce a significant interaction for any given stimulus replication simply by chance, that percentage increases to 40.1 when each subject responds to 10 different stimulus replications. The role of chance returns to 5% when the interaction variance pooled across all replications (i.e., on ten degrees of freedom) for each subject is tested. This approach is statistically comparable to the pooled test for nonadditivity employed by Anderson (1962). Whereas only 25% of Anderson's subjects showed nonadditivity, Table 1 shows that 60% of the subjects in the present study produced significant overall nonadditivity. These results indicate that when the experiment is designed to be maximally sensitive to the effects of differential weighting, a substantial number of people produce statistically significant interactions in the trait-judgment task.

As noted in the presentation of the group data, a number of questions arise in interpreting significant interactions. First, the possibility must be examined that the interactions resulted from response scale nonlinearity rather than from unequal weighting. Second, it is possible that unequal weighting occurred for only a few stimulus replications (e.g., the two that were significant in the group analysis). Third, it may be that all significant interactions are the result of a single stimulus characteristic (e.g., extremely negative traits having a greater weight than all others), in which case all significant interactions for all persons would have the same pattern (as in Figures 1 and 2). The prediction of idiosyncratic weighting, in regard to the second and third above questions, is that all stimulus replications should be involved and that a variety of interaction patterns should be obtained for each replication.

Scale linearity. Although we discarded scale nonlinearity as an explanation for the two significant stimulus replications for the group data, such an explanation could still be viable for a majority of the individuals. Consequently, the pattern of significant and nonsignificant stimulus replication interactions was examined for the 24 subjects (60% of our sample) who displayed overall nonadditivity.

Of these 24 subjects, 14 satisfied the disordinality test by displaying at least one significant disordinal interaction. Of the 10 remaining subjects, 8 satisfied the intersection test for at least one significant interaction. For the remaining 2 subjects (Subjects 28 and 33), it was not possible to dismiss the nonlinearity explanation, since in both cases they showed the same interaction pattern for all 10 stimulus replications. That pattern was consistent with the interpretation that negative stimuli carry more weight than positive stimuli do. However, even after deletion of these 2 subjects, 55% of the sample showed genuine evidence of differential weighting.

Stimulus replications. The possibility remains that such widespread differential weighting is due to a limited number of stimulus replications. Two of the three subjects with significant interaction variance in the Anderson (1962) study were presented with the same stimulus replication.

Out of 400 interactions tested in the present study, 106 were significant. Table 2 shows the distribution of significant interactions over the 10 stimulus replications. It can be seen that the significant interactions were not restricted to just a few stimulus replications. One hundred percent of the replications were involved,

and all contributed approximately equally. For the distribution of interactions over the 10 stimulus replications, $\chi^2(9) = 5.89$, $p > .75$.

An average of 26.5% of the subjects had a significant interaction for the typical stimulus replication. The number of subjects (out of 40) with significant interactions ranged from a low of 7 to a high of 15 over stimulus replications. Even for the most additive of the stimulus replications, 17.5% of the subjects had a significant interaction. In contrast to the findings of the group data, then, it would appear that the pattern of unequal weighting observed in the individual analyses cannot be dismissed as due to only a few stimulus combinations.

Idiosyncratic weighting. The prediction of

Table 2

M	10.6	2.1	8.2

Note. $N = 40$. The terms w_p and w_n refer to the weights given the more positive and the more negative traits, respectively.

idiosyncratic weighting derives from the reasoning that trait meaning and importance is acquired on the basis of each individual's personal linguistic experiences with the word and its referents. It follows from this that for most stimulus replications, some people should weight the negative traits more highly and others should weight the positive traits more highly. Also, when examining the significant stimulus replications for each subject, there should be some subjects who show both patterns of trait weighting. Since the group data showed evidence only of negative traits carrying more weight than positive, we must first ask whether there is any evidence for the opposite pattern in the individual data.

Both ordinal and disordinal interactions can be coded in terms of whether the more positive or the more negative trait is being given the most weight. Of the 103 codable [2] interactions in the present study, 82 (79.6%) were found to have a pattern consistent with the interpretation that negative traits carry more weight than positive traits do. The remaining 20.4% showed exactly the opposite pattern, that is, positive traits carried more weight than negative traits did.

By chance alone, it would be expected that half of the 400 interactions would show a negativity effect and half a positivity effect. At the .05 level of significance, this means that 10 tests should show significant negativity and 10 tests significant positivity. The observed frequencies of 82 and 21 were both significantly greater than the expected frequencies, χ^2s(1) = 531.69 and 12.41, ps < .001, respectively. Unlike previous research at the normative level, clear evidence for a positivity effect is found for some subjects. Table 2 shows that in all but one stimulus replication, there existed at least one subject who weighted the positive traits more than the negative traits. An illustration of this diversity of interaction patterns is provided in Figure 3 for Stimulus Replication 7.

Although there might be individual differences in the propensity to assign greater weight to negative or to positive traits, the notion of idiosyncratic weighting leads us to expect that a substantial number of people will display both weighting patterns over different stimulus replications. Of 23 subjects who provided more than one significant stimulus replication interaction, 9 (or 39%) showed both weighting patterns. This is illustrated for Subject 36 in Figure 4. The remaining subjects split 12 and 2 in showing exclusively higher negative weighting and higher positive weighting, respectively.

Discussion

In contrast to the group data, the individual data indicated that differential weighting in the trait-judgment paradigm was widespread. No stimulus replication was immune and no single pattern of differential weighting (e.g., negative traits receiving more weight) prevailed exclusively. It appears, then, that when a more sensitive experimental design than that used by Anderson (1962) is employed, clear differences emerge between the analyses of group judgments and the analyses of indi-

[2] Three disordinal interactions could not be coded in these terms because the two lines intersected. When such "double disordinality" is present, it is impossible to determine the relative scale values of the stimulus traits for the stimulus replication.

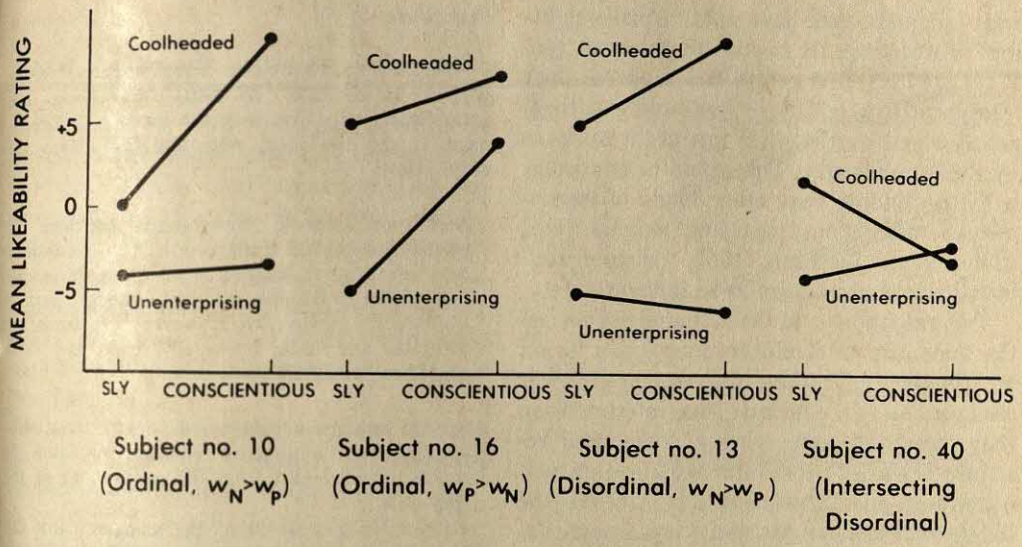

Figure 3. Examples of four different significant interaction patterns obtained for Stimulus Replication 7 in Experiment 1. (The terms w_p and w_n refer to the weights given the more positive and the more negative traits, respectively.)

vidual judgments. Whereas the equal weighting assumption holds for most stimuli at the normative level, idiosyncratic weighting is the dominant feature at the individual level.

Experiment 2

Experiment 2 was undertaken for three reasons. Since the outcome of Experiment 1 stood in direct contradiction to previous assumptions regarding equal weighting of items in the trait-judgment task, a need to replicate the findings was evident. Experiment 2 used the same individual-based design as Experiment 1 but employed 10 new stimulus replications and 80 new respondents.

Whereas Experiment 1 used "naturalistic" instructions, the majority of studies with the

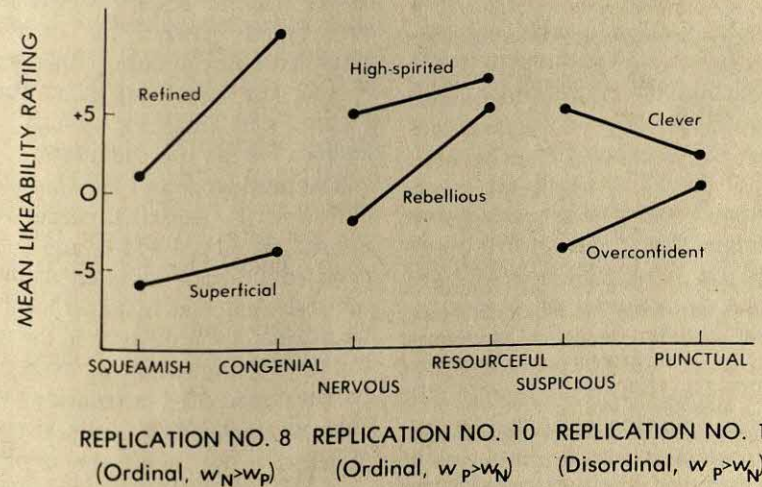

Figure 4. Examples of three different interaction patterns obtained from Subject 36 in Experiment 1. (The terms w_p and w_n refer to the weights given the more positive and the more negative traits, respectively.)

trait-judgment task have used "equal weighting" instructions. It is possible to argue (see Wyer, 1974a) that people can suppress their idiosyncartic weighting of traits and give them nearly equal weight when instructed to do so by the experimenter. This would be consistent with the finding that other kinds of experimenter instructions regarding weights (e.g., Anderson & Jacobson, 1965, "discounting" instructions) are known to be influential.

Two respondents in the first study produced the same form of significant interaction for all 10 stimulus replications. Consequently, it was not possible to eliminate the interpretation that these two were using a noninterval response scale. A procedural modification was introduced in Experiment 2 to reduce the likelihood that subjects would use a noninterval response scale. A total of 20 extreme anchor stimuli preceded and were interspersed among the 40 test stimuli in this study. This leads subjects to use the interior portions of the scale when rating the stimuli (Simpson, Ostrom, & Sloan, 1973) and thereby reduces the influence of any noninterval response tendencies that may intrude into either the positive or negative extremes of the scale. The use of such anchor stimuli has become widely adopted in the trait-judgment paradigm.

Method

Subjects

Subjects were 80 introductory psychology students from Ohio State University, 40 males and 40 females, who participated in partial fulfillment of course requirements.

Stimuli

New stimulus traits were randomly selected from the Edwards (Note 1) list. Subjects judged 40 test stimulus trait pairs from 10 randomly constructed stimulus set replications, where each set consisted of 4 trait pairs produced from a 2×2 factorial design. The two levels of likeability for the two trait factors were M+ and M−, as in Experiment 1. No semantically inconsistent or redundant trait pairs were allowed within a stimulus replication.

In order to adequately anchor the response scale, 12 pairs of extreme anchor stimuli preceded the 40 pairs of test stimuli, and 8 pairs of anchor stimuli were evenly interspersed among the 40 test sets. Half of the anchor pairs were positive, and half were negative.

Procedure

Subjects were given either "equal weighting" ($N = 40$) or "naturalistic" ($N = 40$) instructions. The naturalistic instructions were the same as in Experiment 1, and the equal weighting instructions are given below.

> Each trait is equally important in describing the person. Sometimes, of course, the two words may seem inconsistent. That is to be expected, because each of the two people may see a different part of the person's personality. However, both traits are accurate, and each is equally important. You should pay equal attention to both.

After the experimenter answered any questions, subjects completed a practice booklet containing 15 stimulus pairs sampled from the entire range of the rating scale.

Subjects judged all 60 of the stimulus pairs (20 anchor and 40 test) in the experimental booklets on each of 5 successive days. Ratings were made on a 21-point scale ranging from 0 (dislike very much) to 20 (like very much). Five random orders of test stimuli were Latin square counterbalanced across days. Anchor stimulus pairs always appeared in the same order.

Results

The second experiment differed from the first in two important ways: (a) It employed both equal-weight and naturalistic instructions and (b) it introduced extremely positive and negative anchor stimuli in order to stabilize the response scale. No reliable differences were found between the equal-weight and naturalistic instructions, either for the group data or the individual data. The results in Figure 5 and Table 3 show highly comparable findings for the two conditions.

The introduction of extreme anchor stimuli did have its expected effect. Whereas the means for the M+M+ and M−M− cells deviated 5.0 scale units on the average from the scale midpoint in Experiment 1, they deviated only 3.9 scale units in the second study. Further, the adoption of anchor stimuli apparently succeeded in reducing the number of subjects employing a nonlinear response scale. Whereas in the first study 2 of 40 subjects were identified as possibly using nonlinear scales, none of the 80 subjects in the second study were so identified.

Group Data

As in the first study, the overall interaction was significant, $F(1, 78) = 27.97$, $p < .001$, and as Figure 5 shows, was not significantly reduced under equal weighting instructions, $F(1, 78) < 1$. The total proportion of the between-cells variance contributed by the interaction was .31%. Separate analyses were done for each instruction condition, and the interaction was significant for both, Fs$(1, 39) > 13.87$, ps $< .001$, with neither contributing more than .40% of the between-cells variance (see Table 3).

When tested separately, 4 of the 10 stimulus replications (1, 4, 6, and 10) produced significant interactions, Fs$(1, 3042) > 3.97$, ps $< .05$.[3] Of the 20 stimulus pairs in this study, between 60% and 80% showed no significant departure from equal weighting at this normative level. This is slightly lower than was observed in the first study (for which the comparable estimate was between 80% and 90%). The observed increase in number of significant interactions was due to the doubling of sample size. When each instruction condition was tested separately, only two replications were significant in each (4 and 6).

Three of the four replications satisfied the intersection test and could not therefore be dismissed on the grounds of scale nonlinearity. All significant replications had the same pattern as Figure 5, indicating that when averaged over all subjects, negative stimuli appeared to carry more weight than positive stimuli. There was, however, only modest evidence that the significant stimulus replications contained the most negative traits. Using the lowest marginal mean as an index of each replication's most negative trait, the four significant replications ranked second, third, fourth, and seventh most negative.

Overall, the results for these group data substantially replicate the group results for Experiment 1.

Individual Data

Over three quarters (77.5%) of the subjects had at least one significant interaction. Although this figure was quite comparable to

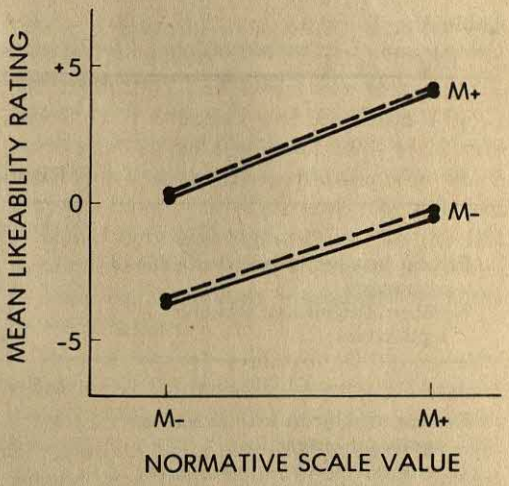

Figure 5. Mean likeability ratings averaged over days, stimulus replications, and subjects in Experiment 2. (M+ = moderately favorable. M− = moderately unfavorable. Naturalistic instructions results are in dashed lines, and equal weighting instructions results are in solid lines.)

that for Experiment 1, there was a reduction in the percentage of subjects who showed significant pooled interaction variance (on 10 and 156 degrees of freedom), from 60% to 46%. Even though this figure is slightly below 50%, it is still substantially higher than a baseline provided either by chance, $\chi^2(1) = 286.30$, $p < .001$, or by the 25% level observed in Anderson's (1962) study, $\chi^2(1) = 19.27$, $p < .001$.

The discrepancy between the two studies is reduced somewhat when those subjects whose interactions might have been the result of nonlinear response scales are eliminated from consideration. Whereas 2 subjects were deleted on these grounds in the first study (reducing the figure to 55%), none were eliminated from the second study (leaving the figure at 46%). In examining the scale nonlinearity interpretation for the 37 nonadditive subjects in the second study, 22 satisfied the disordinality test, and 15 the intersection test.

Stimulus replications. Once again, all stimulus replications contributed approximately equally to the significant interactions obtained

[3] The error term for these analyses was the interaction between stimulus persons (40) and subjects (40) nested within instruction conditions (2).

Table 3
Comparison of Experiments 1 and 2 for Group and Individual Data

Item	Experiment 1	Experiment 2		
		Naturalistic instructions	Equal-weight instructions	Combined
Group data				
Percent between cells variance due to interaction	1.00	.26	.40	.31
Number of significant stimulus replications	2	2	2	4
Individual data				
Percent of subjects with at least one significant interaction[a]	82.5	72.5	82.5	77.5
Percent of subjects with significant pooled interactions[b]	60.0	45.0	47.5	46.25
Percent of stimulus replications with at least one significant interaction	100	100	100	100
Total number of significant interactions	106	57	76	133
Percent of all significant interactions in which:				
$w_n > w_p$	79.6	74.1	78.4	76.6
$w_p > w_n$	20.4	25.9	21.6	23.4

Note. The total number of subjects in Experiment 1 was 40. Experiment 2 had 40 subjects in each of the two instruction conditions. The terms w_p and w_n refer to the weights given the more positive and the more negative traits, respectively.
[a] Chance = 40.1%. [b] Chance = 5%.

at the individual level, $\chi^2(9) = 13.69$, $p > .10$. This occurred, however, despite a substantial decrease in the average percentage of subjects showing a significant interaction for the typical stimulus replication. The figure dropped from 26.5% to 16.6%, with a range, in the second study, from 7.5% to 27.5%.

The decrease in the second study may have resulted from the introduction of 20 extreme anchor stimuli. The anchor stimuli were intended to eliminate some interactions that were due to scale nonlinearity. Since they increased the number of stimulus persons to be judged each day by 50%, however, they may also have induced a more additive integration set by making the task more boring.

Idiosyncratic weighting. Of the 128 codable[4] interactions, 76.6% showed a pattern interpretable as meaning that negative traits carried more weight than positive traits, and 23.4% showed a pattern favoring positive traits. This was very close to the split observed in Experiment 1 (see Table 3). Also, as in Experiment 1, both the number of significant negativity and positivity interactions exceeded chance, $\chi^2(1) = 1624$, $p < .001$, and $\chi^2(1) = 5.13$, $p < .05$, respectively. Instances of both weighting patterns appeared in 8 of the 10 stimulus replications, the remaining 2 containing only interactions in which the negative trait received more weight.

As in the first study, a substantial number of subjects displayed both weighting patterns. Out of the 37 subjects with more than one significant stimulus replication interaction, 35.1% showed both patterns. All but 1 of the remaining 24 subjects gave the negative traits more weight than the positive traits.

Discussion

The results of Experiment 2 replicated the idiosyncratic weighting findings of Experiment

[4] Five disordinal interactions were not codable, four because the lines intersected (see Footnote 2) and one because the marginal means were exactly identical on one of the factors in the 2 × 2 design.

1 and demonstrated as well that idiosyncratic weighting is obtained under both naturalistic and equal weighting instructions. The absence of differences between instruction conditions at the level of group analyses is consistent with several previous studies finding no differences in trait judgments between naturalistic and equal weighting instructional conditions (Anderson & Jacobson, 1965; Gollob & Lugg, 1973; Lampel & Anderson, 1968; Wyer, 1974b). Whereas people appear able to increase differential weighting tendencies when given "discounting" instructions (Anderson & Jacobson, 1965; Kaplan, 1973), they did not reduce their differential weighting tendencies when specifically instructed to weight all traits equally.

General Discussion

The data reported in this article support the conclusion that it is incorrect to describe the integration process in the trait-judgment paradigm as following an equal weighting averaging rule at the level of the individual subject. This conclusion is in contradiction to previous descriptions of the trait-judgment task, descriptions that were based upon the one previous direct test of individual differences in trait weights (Anderson, 1962). The difference in outcomes between this and the Anderson (1962) study can be attributed to the far greater sensitivity of the present experimental design.

Implications for Information Integration Theory

Generality of idiosyncratic weighting. The trait-judgment paradigm is not the only social judgment domain in which differential weighting occurs at the individual level. Significant nonadditivity has been obtained in several other areas. Leon, Oden, and Anderson (1973) found it for 38% of 16 subjects who judged the "badness" of a group of people guilty of committing various crimes; Anderson (1972) obtained it for 83% of 6 subjects who judged, on the basis of behavior items, the severity of psychiatric disturbances; Troutman and Shanteau (1976) observed it for an average of 28% of 20 subjects who judged the quality of disposable diapers in one replication and infant car seats in the others; and Shanteau and Anderson (1969) obtained it for an average of 25% of 20 subjects over four stimulus replications in which subjects rated their preferences for different food and beverage combinations. In the last mentioned study, 65% of the subjects showed at least one significant interaction over the four replications.

This extensive evidence of differential weighting at the individual level was obtained despite the fact that none of the above studies incorporated all of the precautions for maximizing sensitivity employed in the present research. Yet none of these percentage figures are reasonably close to the five percent chance level (although due to small sample sizes, some may not statistically differ from it). It would appear, then, that at present there exists *no* social judgment domain that could plausibly be regarded as an instance where an equal weight averaging integration rule held.

The absence of any verified instance of equal weighting encourages speculation that there may, in fact, exist no social judgment domain for which equal weighting holds. Such a state of nature would follow from the premise that items of social information acquire meaning and importance on the basis of highly individualistic experiences with the signs and symbols conveying that information. Certainly on these grounds, it would seem that any social information conveyed lexically would be susceptible to idiosyncratic weighting differences. A more promising domain where equal weighting may prevail would involve purely sensory stimuli responded to through a nonsemantic mode (as is often done in cross-modality matching).

Normative versus individual levels of analysis. The present studies show that findings obtained at the group (or normative) level do not necessarily replicate for each member of that group. Consequently, it is appropriate to question whether other empirical findings obtained at the group level in the trait-judgment task (e.g., set size, serial position, and inconsistency discounting effects) hold for all indi-

viduals. There are no adequate data presently available that allow us to estimate what percentage of people employ an averaging rule (as opposed to a summative or multiplicative rule) in the trait-judgment task. This possibility of individual differences in integration rule can be illustrated by a study in another social judgment domain (Leon, Oden, & Anderson, 1973). They conducted analyses on individual subject data and found significant set size effects for some subjects and not for others.

The difference in outcome between group and individual responses should not be dismissed as reflecting mere individual differences around a group average. Instead, the two types of data should be regarded as fundamentally different levels of analysis, each appropriate to different scientific objectives.

Data from an individual, when obtained over repeated observations, are definitive for understanding the integration rule used by that person. If the objective is to establish that the typical person uses a particular integration rule, it is necessary to show that most people, when studied as individuals, employ that integration rule. Such a generalization cannot be made on the basis of group data.

This is not meant to dismiss the importance of the multitude of findings previously obtained at the group level. Group data inform us as to the integration rule that characterizes the modal societal reactions made in a particular response domain. At this level of analysis, information integration theory provides estimates of the normative weights and scale values of information items in that domain. It also establishes a normative integration rule for the subject group. This is clearly a descriptive enterprise that need have no implications for how individuals subjectively integrate information. There are many problem areas for which it is of direct interest to study the integration rule underlying the modal group response, areas such as stereotyping, advertising, political preferences, and jury decision making. For example, it is useful to know that jurors in aggregate can presume innocence (Ostrom, Werner, & Saks, 1978), even though this presumption may not hold for all of the jurors considered individually.

Ambiguity of the "parallelism" test. Up to this point in the paper we have chosen to explain deviations from parallelism in terms of unequal trait weights. But to do so requires us to assume that the theoretical scale value of each trait is unaffected by the nature of the other trait in the pair. Unlike trait weight, the scale value is viewed as nonlabile. This assumption has been made in most integration theory interpretations of differential weighting research and has been defended as a legitimate strategy for model building (Himmelfarb, 1975).

Some recent studies (see Ostrom, 1977) have attacked that assumption, and have established the plausibility of scale value lability. The cognitive representation and accompanying evaluative response evoked by a trait appears to be directly affected by the evaluative tone of the context traits. If such meaning shift processes do occur in the trait-judgment domain, the interpretation of deviations from parallelism becomes much more difficult. Significant interactions could be due to differential weighting, scale value shifts (with equal weighting), or to both.

Most of the significant interactions observed in the present studies had an ordinal or disordinal, nonintersecting pattern. These could all be interpreted either in terms of differential weighting or in terms of scale value shift. However, there is one logically possible interaction pattern that, if obtained, could not be explained by a differentially weighted averaging model, namely, a pattern that is both disordinal and intersecting (see the right panel of Figure 3). Given that people are using an averaging integration rule, this pattern could only be obtained if the scale values of the row traits reversed their relative positivity, depending on which column trait they were paired with. Although such patterns were observed in the present studies (three in the first and four in the second), they represented only 2.93% of all significant interactions.

The major findings of the present studies could be explained as easily in terms of scale value shift as they could by differential weighting. Namely, it could be concluded that a majority of the subjects displayed scale value shifts, that all stimuli were capable of undergoing such shifts, and that these shifts

are highly idiosyncratic. For any particular trait pair, some people show greater shift in a negative context, others in a positive context, and other people show no shift at all.

Limitations of a differential weighting averaging model. No fundamental difficulty is created for information integration theory if idiosyncratic weighting proves to be the state of nature in social judgment (or even all judgment) domains. Its objective is, after all, the specification of an integration rule, and determination of whether equal or differential weighting occurs. The problems created are more ones of experimental convenience.

The equal weight averaging model has a remarkably useful feature. When it holds, and when subjects are responding on an interval judgment scale, no interaction should be statistically detectable when orthogonally composed stimulus sets are being judged. This has allowed researchers to draw three important conclusions when such parallelism emerges: (a) An equal weight additive model is appropriate (discarding both unequal weight averaging models and multiplicative models), (b) the interval property of the response scale is validated, and (c) the marginal means offer estimates of stimulus scale values on an interval scale. The empirical procedures needed to discriminate between an averaging model and a multiplicative model, to validate a response scale, and to obtain interval estimates of scale values are much more complicated in the absence of equal weighting.

Another disadvantage is that the trait judgment task cannot be used as a validational baseline for investigating other stimulus domains. For example, Lampel and Anderson (1968) had subjects judge persons described by a photograph and several traits. The traits were factorially constructed, and since no interaction was obtained, the authors concluded that the response scale was validated and that all traits received equal weight. These two conclusions allowed an unambiguous interpretation of an interaction that was obtained between trait valence and photograph attractiveness. The possibility of a nonlinear response scale and the possibility of differential trait weights could both be ruled out because of the absence of a Trait × Trait interaction. This allowed the investigators to conclude (by a process of elimination) that there was a differential weighting of the photographs in which weight was inversely related to photograph attractiveness. The present finding of idiosyncratic weighting would rule out the use of the trait-judgment domain for such purposes in future research at the individual level.

Implications for Person Perception Research

The stimulus domain studied in this research was fairly narrowly defined, being restricted solely to person characteristics in the form of personality trait adjectives. Even that domain, however, was not fully represented in the traits sampled for use in the present studies (from Anderson, 1968). The traits did not include slang terms or adjectives solely descriptive of mood or feeling states (e.g., Bush, 1973). It seems unlikely, however, that either slang or feeling terms would be more characterized by equal weighting than were the sampled adjectives. In fact, slang terms may well be even more prone to idiosyncratic weighting, given respondents who are selected from two or more different social groupings.

There is a wide variety of information items that have been used in person perception research, including personal attitudes, hobbies and interests, demographic characteristics, group memberships, and behavioral acts and intentions. It is, of course, possible (although we do not regard it as probable) that one or more of these categories may represent an equal weighting domain.

Although the present studies were not tailored to investigate the determinants of trait weight, the idiosyncratic weighting findings suggest two possible avenues of exploration. There was some suggestion of individual differences in whether or not weight was associated with scale value. Nearly two-thirds of the subjects who had more than one significant stimulus replication showed the same weighting pattern (either negativity or positivity) for each significant replication. Conceivably, such a dispositional tendency could be related to other individual differences in positivity or negativity in impression judg-

ments (see Kaplan, 1973). A second approach would be to relate trait weight to the personal constructs (Kelly, 1955; Rosenberg, 1977) each individual characteristically uses to describe important others in his or her social world.

The Effect of Situational Contingencies on Female Retaliative Behavior

Deborah Capasso Richardson and Sandy Bernstein
University of Georgia

Stuart P. Taylor
Kent State University

Most studies that have found sex differences in aggression have reported that males are more aggressive than females. Recent evidence, however, suggests that the expectation of female nonaggressiveness may be unwarranted. The present study attempted to reconcile these differences by considering the contingencies of female aggression. Thirty females competed in a task designed to measure aggression (a) alone, (b) in the presence of a silent observer, or (c) in the presence of a supportive observer. Results indicated that as provocation increased, women in the private condition responded more aggressively than did women in the public condition. Also, women who responded in the presence of an audience were more aggressive when the observer was supportive than when she was silent. It is concluded that the usual findings of female nonaggressiveness may be attributable to women's expectations of disapproval for aggressive behavior.

Traditionally, women have been viewed as the nonaggressive sex. Most of the studies that have found sex differences in aggression have reported that males are more aggressive than females. These results have been obtained with children (Liebert & Baron, 1972; Pederson & Bell, 1970; Santrock, 1970; Shortell & Biller, 1970) as well as with adult subjects (Buss, 1966; Doob & Gross, 1968; Epstein, 1965; Youssef, 1968), using various methodologies and different aggression paradigms.

It might appear, then, that females are adhering to a "norm of passivity." According to Maccoby and Jacklin (1974):

> Aggression in general is less acceptable for girls, and is more actively discouraged in them, by either direct punishment, withdrawal of affection, or simply cognitive training that "that isn't the way girls act." Girls then build up greater anxieties about aggression, and greater inhibitions against displaying it. (p. 234)

This response inhibition hypothesis proposes that the female's socialization history causes her to inhibit the display of aggression. Maccoby and Jacklin (1974) suggest that sex differences in aggression may arise because females are reinforced for nonaggressive behavior. Since aggression in general is less acceptable for girls and is more actively discouraged in them by socialization agents, girls have greater anxieties about aggression as well as greater inhibitions against displaying it. Frodi, Macaulay, and Thome (1977), in their review of the literature on sex differences in aggression, note that in the course of normal socialization, women learn to respond to provocation with aggression anxiety and that in our culture aggressive behavior from women is not approved of and receives negative evaluations. Thus, they conclude that "through avoidance or anticipatory arousal of aggression anxiety or guilt, women avoid acting aggressively" (p. 654).

Other evidence, however, suggests that the expectation of female nonaggressiveness may be unwarranted. Taylor and Epstein (1967) found that sex differences in aggression dis-

appeared when women were confronted with increasing provocation by a male opponent in a reaction time experiment. Using the same paradigm, Richardson (Note 1) found no sex differences in response to continually high provocation. In addition, Frodi et al. (1977) concluded that evidence indicates that women do *not* show consistently lesser tendencies to physically aggress than do men.

It is apparent that experimental evidence concerning the aggressiveness of women is contradictory. These differences might be reconciled, however, by looking at the environmental contingencies of female aggression. The variability of findings may result from the presence or absence of elements in the experimental situation that evoke conformity to sex role expectations (Frodi et al., 1977). The socialization process that women in our culture undergo has taught them that in many or most situations, aggression will not be approved of and will receive negative sanctions (Costrich, Feinstein, Kidder, Marecek, & Pascale, 1975). Thus women have learned to inhibit their aggressive behavior. At times, however, in spite of childhood socialization and adult sex role restrictions, women do behave aggressively. This negation of traditional sex role requirements can be explained once certain situational factors have been inspected.

Using a competitive reaction time task, Taylor and Epstein (1967) found that when faced with increasing provocation from a male opponent, women would deliver shocks to their opponent at an intensity equivalent to that set by male participants for male opponents. Since the male opponent violated social expectations by delivering relatively high shocks to a woman, the female participants may have felt that they, also, were excused from the usual sex role requirements. Frodi et al. (1977) note that sex differences in aggression seldom appear when aggression is permissible behavior for women. That is, when aggression is justified or when women are acting anonymously—as a deindividuated member of a group—sex differences in aggression are not found.

The contention that women may drop their stereotypical feminine role and behave in a relatively masculine manner also receives support beyond the area of aggression. In a study conducted by Kidder, Bellettirie, and Cohn (1977), reward allocations were made by male and female participants in either a public or a private condition. In the public condition, each sex conformed to its role expectations. When assured of anonymity, however, both sexes abandoned their traditional sex-typed roles.

The present study was designed to investigate the effects of situational contingencies on so-called female nonaggressiveness. Female participants competed against a male opponent in a reaction time task designed to measure aggression. The participants competed in one of three conditions: (a) private —alone in the experimental room; (b) public—in the presence of a silent female observer; or (c) supportive other—in the presence of a female observer who offered social support for retaliating against the opponent.

It was hypothesized that women in the public condition would behave less aggressively in response to provocation than would women in the private condition. The presence of a silent female observer in the public condition was expected to make salient the traditional sex role expectations for *female* nonaggressiveness (e.g., Frodi et al., 1977) and result in behavior that conformed to the participants' perceptions of what the observer expected of them. Women in the supportive other condition, not having to rely on their perceptions of the observer's expectations and knowing that the observer did not expect nonaggressive behavior, were expected to behave more aggressively than would women in the public condition. It was also hypothesized that women in all three conditions would respond more aggressively as provocation by their male opponent increased.

Method

Participants

The participants were 30 female undergraduates enrolled in introductory psychology classes at a large midwestern university. Participation was in partial fulfillment of course requirements. Ten women were randomly assigned to each of the three experimental conditions.

Procedure

Before initiating the procedure, participants were informed that they would be competing in a reaction time task with the person in the next room, that there would be a slight electric shock involved, and that they had the right to leave the experiment at any time without penalty. Participants were then encouraged to ask questions before signing the informed consent statement, which also served as their record of participation.[1]

The female experimenter seated the participant at the task board (described by Taylor, 1967) and attached a concentric shock electrode to her wrist.

In the public and supportive other conditions, a female observer (confederate) arrived at the door of the participant's cubicle and reminded the experimenter that she was a student whose adviser had recommended that she observe an experiment in progress. After obtaining the participant's consent, the experimenter seated the observer slightly behind and to the side of the participant and then left the room for 5 minutes, presumably to attach the opponent's shock electrode.

In the private condition, no observer was present, but the procedure was otherwise identical to the other two conditions.

The participant's "unpleasantness" threshold was then determined. That is, intensity of shock was gradually increased until the participant reported it to be "definitely unpleasant." This was the maximum intensity administered and was designated as Level 5; 90% of the maximum was designated as Level 4; 80% as Level 3; 70% as Level 2; and 60% of the maximum was designated as Level 1. The participant also overheard a tape recording of a male voice telling the experimenter when the shock was unpleasant for him. Thus, she was led to believe that she was to be competing with a male opponent, although no opponent was actually involved in this experiment.

The participant then heard a tape recording of the task instructions. She was told that at the beginning of each trial she should select any one of the five intensities of shock she wished her opponent to receive at the end of the trial if his reaction time was slower than hers and that she would receive the shock her opponent set for her if she was slower than her opponent.

The trials began immediately after the completion of the task instructions. Each trial consisted of four specific events: (a) the onset of the *set* light, which instructed the participant to press one of the five buttons corresponding to the intensity of shock she wished her opponent to receive; (b) the onset of the *press* light, which instructed her to press the reaction time key; (c) the onset of the *release* light, signaling to the participant that she should remove her finger from the reaction time key as quickly as possible; and (d) the onset of one of the five small red lights at the top of the task board, which indicated the intensity of shock that had been set for the participant by her opponent and, if the opponent was faster, the shock as well.

Each participant competed in 25 trials. These consisted of four blocks of 6 trials each plus an extra trial to measure the participant's reaction to Trial 24. The average feedback settings for Blocks 1 through 4 were 1.5, 2.5, 3.5, and 4.5, respectively. Wins and losses and feedback/shock delivered to the participant were programmed by the experimenter. The participant was led to believe that she had won 50% of the trials within each block.

In the supportive other condition, the observer initiated conversation with the participant during the first block of trials, speaking in a friendly, spontaneous manner and sympathizing with her whenever she lost a trial. As the attack increased in the later blocks of trials, the observer attempted to encourage the participant to reciprocate by commenting upon the male opponent's behavior ("he went up there a little bit," "he gave a three!"); indicating that if she were competing with the opponent, she would retaliate ("I wouldn't let him get away with that!", "I don't think I'd let him step all over me"); and suggesting that the participant reciprocate ("Another 4! Maybe you should give it back"). At no time did the observer suggest initiating attacks or setting higher intensity shocks than the opponent. The observer in the public condition remained silent throughout the experimental session.

Following the competition task, women in the public and supportive other conditions were asked to rate the observer on a series of 6-point bipolar adjective scales.

Results

Aggression was measured by the magnitude of shock the participants set for administration to their opponent. Participants were required to select a shock intensity on the first trial without any knowledge of the aggressive intentions of the opponent. As expected, there were no significant differences among conditions in the initial trial, $F(2, 27) = .20$, *ns*.

A 3 (Group) × 4 (Blocks) analysis of variance was performed on mean shock intensities set during the four blocks of trials in order to examine changes in shock settings over blocks. There was no significant main effect for group, $F(2, 27) = 2.24$, *ns*. However, the interaction between groups and blocks was significant, $F(6, 81) = 4.66$, $p <$

[1] This statement indicated that the participant understood (a) the purpose of the experiment, (b) any risks that might be involved, (c) that she could leave the experiment at any time without penalty, and (d) that the details of the experiment would be explained after participation was complete.

.0005. According to Newman–Keuls analyses, as the trials progressed, women in the private and supportive other conditions responded in an increasingly more aggressive manner than did women in the public condition ($p < .05$). Figure 1 demonstrates this relationship and the similarity of the behavior of participants in supportive other and private conditions.

The mean shock intensities set by women in the private condition in Blocks 1 through 4 were 1.52, 1.97, 2.68, and 3.20, respectively. Women in the supportive other condition set mean shock intensities of 1.60, 1.90, 2.79, and 3.57 in Blocks 1 through 4, respectively. However, women in the public condition evidenced less increase by setting mean shock intensities of 1.73, 1.58, 2.12, and 2.03 in Blocks 1 through 4. Further analysis revealed that the differences in mean shock settings were significant only in the final blocks of trials.

As predicted, there was a significant main effect of blocks, $F(3, 81) = 36.22$, $p < .001$, indicating that shock settings, in general, increased over blocks. The mean shock intensities set in Blocks 1 through 4, respectively, were 1.62, 1.85, 2.53, and 2.93.

Following their participation in the competition task, women in supportive other and public conditions were asked to rate the observer on a series of 6-point adjective scales with a midpoint of 3.5. Analysis of this data by t tests indicated that the observer in the supportive other condition was perceived to be significantly more friendly (4.90 vs. 3.90), good-humored (5.50 vs. 4.60), happy (4.40 vs. 3.60), honest (4.60 vs. 3.40), and sociable (4.70 vs. 3.60) than was the observer in the public condition. Also, the observer in the public condition was perceived as being significantly less revengeful (1.40 vs. 3.40), less competitive (2.40 vs. 4.10), less aggressive (2.30 vs. 4.00), and more passive (3.60 vs. 2.00) than was the observer in the supportive other condition (all $ps < .05$).

Discussion

The present study attempted to delineate the effects of situational contingencies on female aggression. It was assumed that women would respond to provocation less aggressively in the presence of a silent audience than when they were either alone or in the presence of a supportive audience. Both hypotheses were supported. Women in the private condition responded to the male opponent's provocation by setting higher shocks than the women who participated in the presence of a silent observer. Similarly, women who were encouraged by the audience retaliated at higher levels than did those who received no such social support.

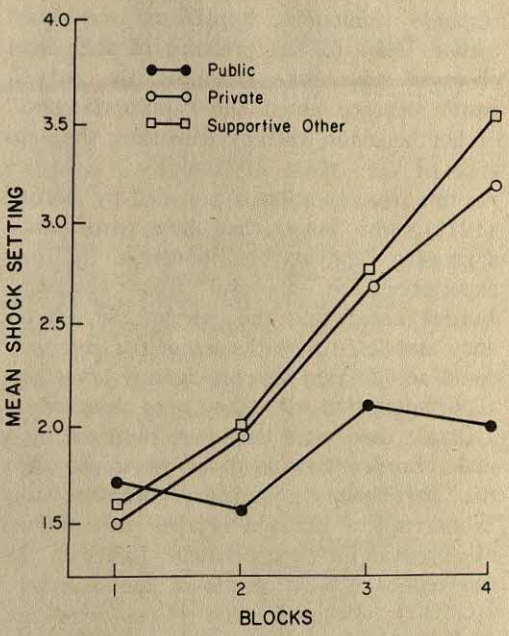

Figure 1. Mean shock settings as a function of group and block.

As predicted, situational contingencies influenced female retaliative behavior, thereby bringing into question the common assumption of female nonaggressiveness. Indeed, it appears that the aggressiveness of women was largely determined by the contingencies present. When reciprocal responding was clearly called for, as in the supportive other condition, women retaliated. When their response was relatively anonymous, as in the private condition, women retaliated. The only situation in which nonaggressiveness was evidenced was in the presence of a silent observer in the public condition. In this case, one might expect that the women were responding to the assumed expectations of the audience.

The relatively low level of aggression in the public condition lends support to the

response inhibition hypothesis mentioned earlier. That is, the presence of the silent observer may have increased the participant's concern about the "appropriateness" of her behavior, thereby enhancing the salience of the "norm of passivity." Evidence for this interpretation is provided by Borden (1975), who found that male participants' aggressive behavior was influenced by their expectations of approval from observers. Borden noted that the "generalized expectancy associated with the sex of the observer" could account for his participants' lower levels of aggression when they were observed by a female than when they were observed by a male. Borden concluded, as we might, that the participants' aggressive behavior was "apparently a function of their expectations of approval for such behavior, based on the inferred or explicit values of the observer" (p. 567). Although such values were not explicit in the present study, participants did attribute characteristics consistent with the "norm of passivity" to the silent observer. They perceived her to be relatively nonrevengeful, noncompetitive, nonaggressive, and passive. The participants in the public condition apparently adapted their retaliative responding in accordance with this expectation.

Similarly, behavior of participants in the supportive other condition was consistent with expectations of the observer. The contingencies in that situation reinforced reciprocation of the opponent's behavior. Thus, expectations were no longer for nonaggressive responding and the female participants could reject the "norm of passivity" and still respond in a manner that would conform to the apparent values of the observer. It was not necessary for these women to inhibit their aggressive behavior due to fear of negative sanction for "out-of-role" behavior.

Emotion Recognition: The Role of Facial Movement and the Relative Importance of Upper and Lower Areas of the Face

John N. Bassili
University of Toronto
Toronto, Canada

In order to investigate the role of facial movement in the recognition of emotions, faces were covered with black makeup and white spots. Video recordings of such faces were played back so that only the white spots were visible. The results demonstrated that moving displays of happiness, sadness, fear, surprise, anger and disgust were recognized more accurately than static displays of the white spots at the apex of the expressions. This indicated that facial motion, in the absence of information about the shape and position of facial features, is informative about these basic emotions. Normally illuminated dynamic displays of these expressions, however, were recognized more accurately than displays of moving spots. The relative effectiveness of upper and lower facial areas for the recognition of these six emotions was also investigated using normally illuminated and spots-only displays. In both instances the results indicated that different facial regions are more informative for different emotions. The movement patterns characterizing the various emotional expressions as well as common confusions between emotions are also discussed.

The communication of emotions through facial expression has received considerable attention since Darwin's (1872) analysis of this phenomenon in humans and animals. A variety of issues have been investigated through the years: Can observers recognize emotions accurately? Are facial expressions genetically prewired? If so, can it be demonstrated that they are universally recognizable? What is the relative contribution of contextual information and facial expressions to the recognition of emotions? Do different emotions define points in a multidimensional space, or are they organized into distinct categories?

Underlying these questions is the problem of delineating the facial patterns that give rise to the judgment of different emotions. This direction has variously been referred to as "psychophysical approach" (Frijda, 1968) or "judgment approach" (Ekman, Friesen, & Ellsworth, 1972). It involves the description of information in the face that leads observers to specific judgments of emotions.

Several studies have investigated this problem by presenting subjects with photographs of emotional expressions and analyzing the relationships between components of the expressions and judgments made by observers (Ekman, Friesen, & Tomkins, 1971; Frijda, 1968; Frijda & Philipszoon, 1963; Frois-Wittmann, 1930; for a review see Ekman et al., 1972). Two features of such experiments are notable. The first is that judgment studies of emotional expression have relied on static representations of facial expressions (photographs).[1] Several authors have criti-

[1] Ekman and Friesen's (1978) Facial Action Coding System is a notable exception to this assertion. Empirical research is needed, however, to establish correspondences between the system and specific emotions (see Ekman & Oster, 1979, for a brief review).

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3711-2049$00.75

cized the use of such stimuli. For example, Bruner and Taguiri (1954) point out that "it is rare to the vanishing point that judgment ever takes place on the basis of a face caught in a state similar to that provided by a photograph snapped at 20 milliseconds" (p. 638). Nevertheless, Ekman et al. (1972) have argued that frozen representations of the apex of facial movement provide an economical record of emotional expressions. Moreover, many studies using such records have demonstrated the *sufficiency* of static information for the recognition of emotions (see Ekman et al., 1972; Izard, 1971, for reviews).

The second notable feature of judgment studies concerns the type of description of facial information yielded by the analysis of static stimuli. Such descriptions have invariably analyzed the face in terms of the position and shape of features and wrinkles. For example, Frois-Whittmann (1930) analyzed the face in terms of brow, upper lid, lower lid, nostril, and so forth. Other researchers (e.g., Ekman & Friesen, 1975; Frijda & Philipszoon, 1963; Leventhal & Sharp, 1965) have also offered such feature-based analyses of the face. Moreover, Ekman, Friesen, and Tomkins (1971) state that in devising their Facial Affect Scoring Technique, "a decision was made to describe the appearance of the face primarily in terms of wrinkles, of tension or relaxation in specific features, and of positions of features" (p. 40).

Feature-based descriptions derived from static stimuli ignore several forms of facial information relevant to the judgment of emotions. For example, Ekman and Friesen (1975) discuss situations where the rate at which an emotion is expressed modifies the meaning of the expression. One such case is the very brief expression of disgust implying that the person is not actually feeling the emotion but may be referring to something disgusting.

Another kind of facial information overlooked in the analysis of static stimuli concerns the structured deformations of the surface of moving faces. In a recent experiment, Bassili (1978) argued that because facial muscles are fixed in a certain spatial arrangement, the deformations of the elastic surface of the face to which they give rise during facial expressions may be very informative in the recognition of emotions.

In order to investigate facial movement independently of feature-based information that could be captured in a static record of the face, Bassili (1978) covered faces with black makeup and placed white spots in a random order over them. Using a technique pioneered by Johansson (1973), the faces were videotaped and played back on a television monitor adjusted for maximum contrast and low brightness so that only the white spots were visible. The results of Bassili's (1978) experiment demonstrated that observers were more accurate in recognizing several basic emotions on the basis of facial movement alone than would be expected by chance. However, accuracy rates increased significantly when the faces of actors were fully visible.

Bassili's (1978) experiment suffered from two problems. First, because the actors had not been trained in the expression of emotions, recognition rates, even under conditions where the face was normally illuminated, were not always very high (e.g., 31% accuracy in the recognition of expressions of happiness, when 16.7% accuracy could be expected by chance). Second, so many white spots were attached to the faces (around 100) that the outline of features could occasionally be detected. Since no control conditions exhibiting the blackened faces statically at the apex of the expressions were included in the experiment, it is not possible to state with certainty that the better-than-chance recognition rates were caused by motion information alone.

The present experiment investigates the role of facial motion using actors trained in the expression of emotions, as well as conditions minimizing the presence of feature-based information in the records of expressions. The criterion for the latter aim is that the emotions should not be recognizable if the array of white spots is frozen at the apex of expressions. Control conditions using such static arrays were included in the experimental design.

Another issue investigated in the present experiment involves the division of the face

into an upper and lower area. Ekman et al. (1972) have reviewed research investigating the relative importance of different facial areas in judgments of emotions. Of the seven studies relevant to this issue, two suggested that the mouth area is dominant (Dunlap, 1927; Ruckmick, 1921), two found that no facial region is dominant (Coleman, 1949; Frois-Wittman, 1930), and three suggested that different areas are important for different emotions (Hanawalt, 1944; Nummenmaa, 1964; Plutchik, 1962).

These contradictions were probably caused by the fact that few factors were standardized across experiments; the number of actors, their training, and the type of record employed, as well as the emotions portrayed, varied across experiments. For example, Dunlap's (1927) conclusion regarding the superiority of the mouth area was based mainly on judgments of happiness. This finding does not contradict results from experiments suggesting that different areas are important for different emotions (e.g., Hanawalt, 1944, also found the bottom of the face to be dominant in judgments of happiness).

Since the present experiment benefits from recent developments in research on the recognition of emotions (i.e., the use of several trained actors, as well as the choice of six categories of emotions that have received considerable attention in the past), it was decided to investigate again the relative importance of the upper and lower face in judgments of emotions. Moreover, this would afford a comparison of different facial areas under conditions where only facial motion serves as information.

Method

Overview

Six actors were video-recorded while expressing happiness, sadness, fear, surprise, anger, and disgust. The first independent variable (illumination) consisted of either normally illuminated faces or faces covered with black makeup and white spots. A second variable (area) was cross-cut with the illumination variable and consisted of full faces, upper faces, or lower faces. Since six actors expressed each of six emotions in two illumination and three area conditions, a total of 216 moving displays were shown to subjects. Following these displays, subjects were shown 36 static displays depicting the apex of the six emotions expressed by each of the actors in the spots-only/full face mode. Following each display, subjects chose from among the six labeled emotions expressed in the display.

Subjects

Ten male and 10 female volunteers drawn from an introductory course in psychology served as subjects in the experiment. They were paid $5 for their participation.

Stimulus Materials

Twenty students enrolled in a laboratory course in social psychology were trained in the expression of emotions. The students were provided with photographs of emotional expressions prepared by Ekman and Friesen (1975). Each of the emotions—happiness, sadness, fear, surprise, anger and disgust—was represented in two photographs. Underneath the photographs was a written description of the facial features critical to an expression. Students were given a week to practice their skills at duplicating the expressions shown in the photographs. At the next meeting, students paired up and helped each other perfect their expressions. Each student was then video-recorded while expressing the six emotions. The quality of each expression was later rated by all students in the class with the exception of the actor. The six actors receiving highest ratings (four males and two females) were retained for further class research and were later approached for participation in the present experiment.

Each actor was first recorded prior to the application of makeup. The expression of the six emotions was recorded under three conditions: full face, upper half of the face, and lower half of the face. The division of the face into upper and lower regions was accomplished by having the actor hold a rectangular piece of cardboard in front of the area to be masked. The horizontal edge of the mask was placed slightly below the bridge of the nose. Next, the actors were made up in black, and about 50 white spots, 8 mm in diameter, were affixed to their faces in a haphazard or quasi-random arrangement. The recording procedure was then repeated.

These recordings yielded 216 single displays of an emotion, each lasting about 3 sec. The order of the expressions was randomized and divided into two blocks of 108 displays. The order of presentation of the two blocks was counterbalanced across subjects. These presentations were preceded by 36 practice trials and were followed by 36 control trials. The control displays consisted of a 30-sec static presentation of the apex of each of the six emotions expressed by the six actors under spots-only/full face conditions. The order of these displays was also randomized.

Procedure

Subjects took part in the experiment in pairs and were separated by a large partition. They were seated 4 ft. (1.2 m) from two 11-in. (28-cm) Sony television monitors. One monitor was adjusted for normal viewing, whereas the other had its brightness and contrast levels adjusted so that only the white spots were visible in spots-only conditions. The experimenter switched the monitors on and off for the appropriate displays.

Each display was followed by a 10-sec interval for responses. The responses were made on a short questionnaire containing 300 sets of the six emotion labels. Subjects simply checked which of the six labels corresponded best to the emotion portrayed in a display. They were warned at the outset of the experiment that only white spots that had been placed on the faces of actors would be visible in certain displays, whereas other displays would only show the upper and lower half of the face. Moreover, the practice trials contained an example of each of the conditions.

Results and Discussion

The results can be presented most clearly if the following three issues are considered in order: comparison of accuracy rates in moving and static spot displays; analysis of accuracy rates, using a 2 (Sex) × 2 (Illumination) × 3 (Facial Area) × 6 (Emotion) repeated measures analysis of variance (ANOVA); and analysis of movement patterns and confusions. The accuracy rates used in the statistical analyses were computed by giving subjects a score representing the proportion of displays of an expression, as portrayed by the six actors, that they recognized accurately.

Comparison of Moving and Static Displays

One of the main questions addressed by the present research concerns the sufficiency of motion information for the recognition of emotions. To answer this question, the accuracy rates yielded by spots-only/full face displays were compared with those yielded by static displays of the same faces at the apex of expressions. A 2 (Sex) × 2 (Motion) × 6 (Emotion) ANOVA with repeated measures on the last two factors was used for this analysis. It revealed that moving displays yielded on the average ($M = 52.7\%$) significantly higher recognition rates than static displays did ($M = 29.5\%$), $F(1, 90) = 192.29$, $p < .01$. The effect of sex and emotion will receive attention in the next section. Table 1 shows the mean accuracy rates relevant to the present analysis.

Since the ANOVA also received a significant interaction between motion and emotion, $F(5, 90) = 11.37$, $p < .01$, tests of simple main effects were performed to verify the effect of motion on each emotion individually. These tests indicated that the recognition rate in the case of all six emotions under movement was superior to the recognition rate under static conditions, $F(1, 18) > 9.4$, $p < .01$ in all cases. The recognition rate in each static condition was also compared with expected chance performance. These comparisons revealed that only in the case of happiness and surprise was recognition of static displays significantly more accurate than chance, $t(19) = 2.83$ and $t(19) = 7.59$, respectively, $p < .01$, one-tailed in both cases.

Accuracy Rates in Overall Factorial Design

The next two questions addressed by the present research concern the comparison of normally illuminated moving faces with faces where only facial motion is visible, and the

Table 1
Recognition Accuracy in Moving and Static Displays

Emotion	Happiness	Sadness	Fear	Surprise	Anger	Disgust	*M*
Face							
Moving	90.0	44.2	43.3	88.3	39.2	53.3	59.7
Static	30.8	25.8	12.5	47.5	16.7	21.7	29.4
Difference	59.2	18.4	30.8	40.8	22.5	31.6	
M	60.4	35.0	27.9	67.9	27.9	37.5	

Note. Numbers represent recognition accuracy. The accuracy rate expected by chance is 16.7.

lative effectiveness of the upper and lower gions of the face for the recognition of the rious emotions.

A 2 (Sex) × 2 (Illumination) × 3 (Facial rea) × 6 (Emotion) repeated measures NOVA was used to analyze subjects' accuracy ites. All main effects were significant. Female ubjects ($M = 68.1\%$) were on the average ore accurate than male subjects ($M = 1.6\%$), $F(1, 18) = 6.85$, $p < .025$. Displays f normally illuminated faces ($M = 77.3\%$) ielded higher recognition rates than displays f moving spots did ($M = 52.3$), $F(1, 18) = 70.31$, $p < .001$. Full face displays ($M = 4.4\%$) were recognized more accurately than ere displays of the bottom of the face ($M = 4.9\%$), which were in turn recognized more ccurately than displays of the top of the face $M = 55.1\%$), $F(2, 36) = 50.40$, $p < .001$ multiple comparisons by Scheffé tests yielded values smaller than .01 in all cases). Finally, the main effect due to emotions, $F(95, 0) = 20.50$, $p < .001$, indicated that surprise ($M = 82.2\%$) and happiness ($M = 9.6\%$) were recognized more accurately than ere sadness ($M = 60.8\%$), anger ($M = .9\%$), fear ($M = 57.6\%$), and disgust $M = 49.7\%$) ($p < .01$ by Scheffé tests in 1 cases).

Three two-way interactions were also significant. An Illumination × Emotion interaction indicated that the superiority of normally illuminated displays over spots-only displays was evident in anger, sadness, disgust and fear but not in surprise and happiness, $F(5, 90) = 58.94$, $p < .001$. Moreover, an Illumination × Facial Area interaction indicated that the superiority of normally illuminated displays was particularly pronounced under conditions where the full face was presented, $F(2, 36) = 5.47$, $p < .01$. Finally, a Facial Area × Emotion interaction indicated that the lower region of the face was superior to the upper in the recognition of happiness and disgust, the upper region was superior to the lower in the recognition of anger and fear, and facial region made little difference in the recognition of surprise and sadness, $F(10, 180) = 10.59$, $p < .001$.

The three-way interaction between illumination, facial area, and emotion was also significant, $F(10, 180) = 4.98$, $p < .001$. It reflected the fact that a facial area dominant in a normally illuminated display was not necessarily dominant in a spots-only display (see Figure 1).

The results yielded by this analysis are relevant to several issues addressed by past

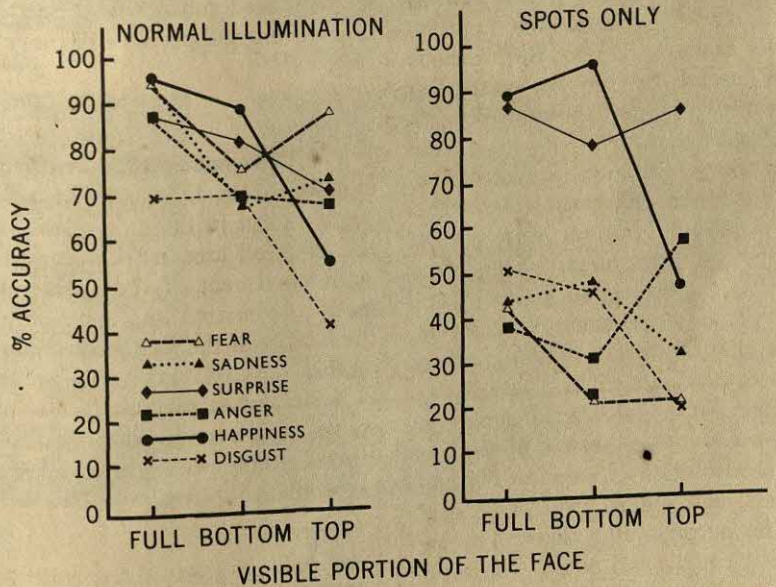

Figure 1. Recognition rates for the six emotions yielded by the three facial areas under normal illumination and spots-only conditions.

research. First, the main effect due to emotions can be compared with a number of studies using posed expressions. For example, Ekman et al. (1972) present a table of "Accuracy Studies of Posed Behavior" (p. 103). Averaging over the studies described in this table, happiness appears to be the easiest emotion to recognize. The results of the present experiment are in basic agreement with this, though surprise achieved an even higher accuracy rate. On the other side of the scale, the recognition of disgust was particularly poor in the present study. This was not generally the case in past research. The reason for the inferiority of disgust in the present study is not clear and could be due to problems in the training of actors. Another finding relevant to past research has to do with the fact that women subjects in the present study achieved significantly higher recognition rates than men did. This finding is consistent with past research (Ekman & Oster, 1979).

The results yielded by the normally illuminated displays are of particular relevance to past research on the relative importance of the upper and lower regions of the face for emotion recognition. The present results suggest that the bottom of the face is more useful than the top for the recognition of happiness, surprise, and disgust, whereas the opposite is indicated for sadness and fear. Both regions were equally useful for the recognition of anger. These results support the general proposition that the importance of upper and lower facial areas for emotion recognition depends on the emotion (Ekman et al., 1972). Given the variability and inconsistency of results yielded by past research concerned with the relative importance of various facial areas in the recognition of emotions, however, it is difficult to compare the present findings with specific results yielded by past studies.

In conditions where only facial movement serves as information, the bottom of the face seems more useful for the recognition of happiness, sadness, and disgust, whereas the reverse holds for surprise and anger. The two regions yielded equal (and poor) recognition rates for fear. The results should be approached with caution because the recognition rates with the exception of happiness and surprise were relatively low and in some cases did not differ substantially from expected chance performance. The type of facial motion information relevant to the various emotions is, however, considered further in the next section.

Movement Patterns and Confusions

This section analyzes the patterns of facial movement yielded by the expression of six emotions. The analysis is accomplished with the help of photographs depicting the paths of the white spots over the course of the expressions (see Figure 2). In addition, a descriptive analysis of major confusions is undertaken (see Table 2). For this purpose an arbitrary cutoff point of 20% was used to isolate emotions that were often confused with a target emotion.

Happiness

The movement pattern yielded by the expression of happiness consists of an upward displacement of each side of the mouth and the cheeks. This movement results from a smile. Following the 20% criterion, happiness was confused substantially only with sadness in spots-only/upper face displays (23.3%).

Sadness

The movement pattern yielded by sadness is more subtle. It consists of a slight upward displacement in the area of the chin, whereas the forehead area reflects an inward and upward movement of the eyebrows. Both normally illuminated and spots-only displays of the bottom of the face yielded confusions with disgust (23.3% and 30.0%, respectively). However, when the full face or top face was shown in spots-only displays, confusions occurred mainly with fear (22.5% and 25.8%, respectively).

Fear

Fear involves a downward and outward movement in the mouth area. The forehead

movement is similar to that of sadness (inward and upward), although the movement is more pronounced because the brows are raised higher. The similarity of movement in the forehead area in sadness and fear is reflected by the fact that in spots-only/upper face conditions fear was often confused with sadness (24.2%). In addition, fear in these displays was confused with surprise (25.8%). This latter confusion was probably caused by the strong upward movement of the brows characterizing the expression of surprise. Another common error yielded by the expression of fear involved happiness and occurred in spots-only/lower face displays (35.8%).

Surprise

Surprise was one of the easiest emotions to recognize, and was particularly so in spots-only displays. The expression involves a strong upward displacement of the brows and an equally strong downward displacement of the jaw. The rapidity of the movement (akin to a startle) is also specific to this emotion. Major confusions only occurred with fear in normally illuminated/upper face displays (28.3%).

Anger

The expression of anger involves a downward movement in the forehead area caused

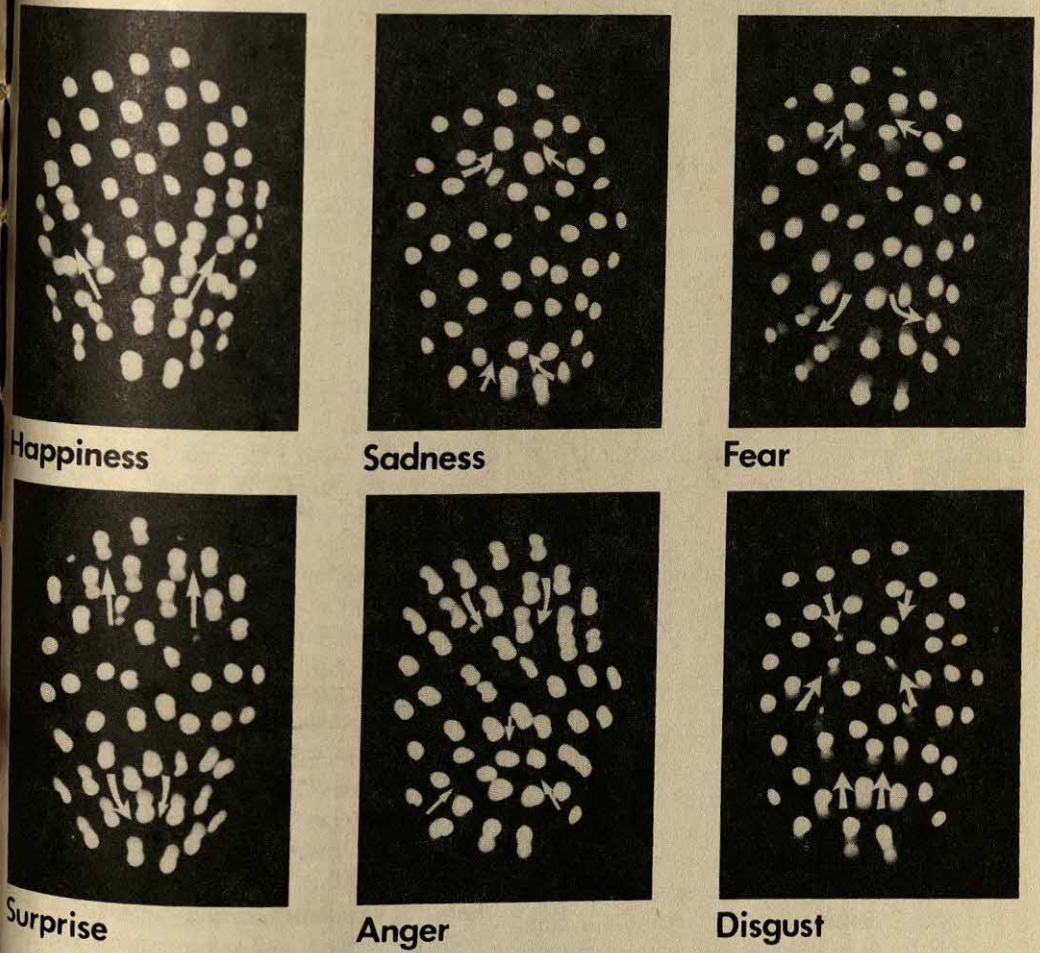

Figure 2. Movement patterns yielded by each of the six emotions investigated. (These photographs represent time exposures of actual television displays. The shutter was opened just before the onset of an expression and was closed just after the expression reached its apex. The arrows indicate the direction of movement.)

Disgust	.8/0	3.3/18.3	2.5/10.0	0/5.8	51.7/46.7	41.7/19.2

Note. The numbers represent the percentage of choices of a column label in response to the display of an emotion described by a row label; numbers on the left of the slash are for responses to normally illuminated displays, and those on the right are for responses to spots-only displays.

by a frown, along with a compression in the mouth area, caused by the pinching of the lips. Anger was confused with disgust in lower face displays (both normally illuminated and spots-only conditions, 20.8% and 25.0% respectively). The normally illuminated/upper face displays yielded confusions with fear (20.0%). Finally, all spots-only displays yielded confusions with sadness (full face = 32.5%, lower face = 20.0%, upper face = 23.3%).

Disgust

The expression of disgust involves the wrinkling of the nose, which causes an upward movement on its sides as well as on the cheeks. Moreover, the expression can involve an upward movement in the area of the chin. Though the wrinkling of the nose is specific to disgust, this emotion leads to low recognition rates. Confusions, however, seemed to concentrate on anger. In all conditions except spots-only/bottom face displays (15.8%), anger was taken for disgust on more than 28% of the trials. This confusion was particularly pronounced in upper face displays (normal illumination = 51.7%, spots-only = 46.7%). The spots-only/bottom face displays lead to confusion with fear (20.0%).

One possible cause of confusions among emotions is that their expressions are so similar that they are difficult to discriminate. If this is the case, confusions should be reciprocal. This was seldom the case in the confusions just described. Reciprocity was only evident in two cases: fear and sadness in spots-only/upper face displays and disgust and anger in normal illumination/bottom face displays. Another possibility is that the actors failed to represent emotions adequately. This possibility, with one exception, is not very likely, since recognition rates in normally illuminated/full face displays were very high (above 87%). The exception involves expres-

ons of disgust (70%), which were often idged as anger.

The third possibility accounting for non-eciprocal confusions is that specific expres-ons may have been nondistinct or ambig-ous. In resolving the ambiguity, subjects ay have responded with an emotion sharing me components with the target emotion. he expression of that alternate choice may ave also been ambiguous and shared compo-ents with yet other expressions. In short, two mbiguous expressions need not be resolved in reciprocal manner.

Conclusion

The present experiment demonstrates learly that movement of the surface of the ace can serve as information for the recogni-ion of emotions. It is not proposed, however, hat such information is generally necessary or the purpose. Much past research using tatic stimuli has demonstrated that facial eatures, with their specific shapes and spatial rrangement, also provide very rich informa-ion for the recognition of emotions. Thus, it ppears that under natural conditions of ob-ervation the observer has access to a redun-lant system of facial information.

The issue of redundancy is complex and is manifested in a variety of ways in emotion ecognition. For example, although the pres-nt research has emphasized the distinction between feature-based static information and purely transformational movement informa-tion, each of these types of information is in turn internally redundant. Specifically, most emotions are represented in specific ways in various areas of the face. It is precisely this characteristic that has led some researchers to inquire about the relative importance of different areas of the face in emotion recogni-tion.

The findings yielded by such research, how-ever, have been complex and inconsistent. This has probably been caused by the fact that emotional expressions contain many cues that serve as information for recognition. By dividing the face into two or three regions, researchers have presented observers with selected subgroups of cues. Some more or less distinctive cues have fallen into the various groups as different emotions were considered, leading to the finding that no facial region dominates across emotions. In order to avoid this haphazard approach to the analysis of dominance in facial information, it would appear desirable for future research to de-lineate the cues relevant to expressions of specific emotions and to scale their relative information value.

Another issue relating to redundancy and more directly relevant to the distinction be-tween feature information and movement in-formation has to do with the nature of their cooperation in the specification of emotions. Specifically, is the observer in a better posi-tion to recognize emotions accurately on the basis of both kinds of information than he/she would be by using the better of the two alone? This question is particularly important in the context of the two types of information discussed here, since they are perfectly cor-related, that is, cannot vary independently. Although an empirical answer to this question will have to await future research, it is likely that the advantage of redundant information manifests itself under poor conditions of ob-servation. For example, movement may render slight or brief expressions more detectable by highlighting the contrast between the appear-ance of the face at two points in time. In a reciprocal manner, features that tend to be points of high contrast on the face may serve as particularly effective "carriers" of motion, thus rendering movement information more detectable.

Research aimed at verifying these specula-tions would have to take another issue into account. In the present research it was deemed appropriate to establish the usefulness of movement information under optimal con-ditions for the recognition of emotions. Thus, the posed "stereotypic" expressions of trained actors were used in the generation of the stimulus displays. When the concern shifts to the specific interaction of feature and move-ment under less than ideal conditions of ob-servation, the research should utilize more ecologically valid stimuli.

Psychological Masculinity and Femininity and Typical and Maximal Dominance Expression in Women

Helen M. Klein and Lee Willerman
University of Texas at Austin

Four groups of women differing in psychological masculinity and femininity as measured by the Personal Attributes Questionnaire, participated in two laboratory situations designed to measure their typical and maximal dominance expression. Typical dominance refers to one's average expression of the trait, whereas maximal dominance refers to one's response capability regarding the trait. As predicted, undifferentiated and feminine women were significantly less dominant than masculine and androgynous women were in both laboratory situations and as measured by the California Psychological Inventory (CPI) Dominance scale. Traditional prescriptions for sex role behavior also affected women's performance in the typical laboratory, where they were significantly less dominant with male confederates than with female confederates, but not in the maximal laboratory, where they were equally dominant with male and female confederates. However, women were more talkative with male confederates rather than female confederates in both laboratory situations. Multiple regression analysis revealed that the CPI Dominance scale was the most effective predictor of laboratory behavior.

Traditional conceptualizations of masculinity and femininity have become the target of much criticism. Many contemporary psychologists have rejected the unidimensional bipolar model in favor of a dualistic approach, that masculinity and femininity are independent dimensions and coexist to some degree in everyone (Bem, 1975; Block, 1973; Constantinople, 1973; Spence, Helmreich, & Stapp, 1974).

One major source of dispute in this literature is the diversity of definitions of "sex roles." Under this heading, investigators have included all of the behaviors, attitudes, preferences, and internal dispositions differentiating men from women. This state of affairs can be attributed in part to the widespread assumption that "biological gender, masculine and feminine sex-role behaviors, and the psychological attributes of masculinity and femininity are tightly intercorrelated" (Spence & Helmreich, 1978, p. 10).

If these qualities are only weakly related, however, it becomes imperative to distinguish between masculine and feminine sex roles (defined as overt behaviors deemed appropriate for members of each sex in certain situations) and internal dimensions of masculinity and femininity (defined as agentic and communal traits, Bakan, 1966).

A study by Megargee (1969) on dominance expression illustrates this distinction nicely. When high dominant women (as defined by the California Psychological Inventory or CPI) were paired with low dominant men on a leader–follower task, the women did not often take on the role of leader. These women, however, actively chose the leader 69% of the time, and when they did, they selected the men 90% of the time. In this way the women asserted their dominance without violating traditional sex role standards.

What if traditional sex role prescriptions

were relaxed? Would correlations between psychological dimensions of masculinity or femininity and behavior become more or less pronounced? One way to do this is by requiring subjects to perform under maximal conditions (Fiske & Butler, 1963; Wallace, 1966; Willerman, Turner, & Peterson, 1976).

These authors have distinguished between typical and maximal performance. The former refers to one's usual or average behavior, and the latter refers to one's maximum expression of the trait-linked behavior under conditions designed to elicit it to the greatest degree. Traditional laboratory situations, based on a typical performance format, often produce idiosyncratic differences in levels of motivation as well as differences in the interpretations of the task at hand. Laboratory situations based on a maximal performance format, however, explicitly encourage the individual to focus on one specified extreme of a target trait to determine what he or she can do. This ought to lead to greater homogeneity in motivational level and clarity about the demands of the situation. In this context, socially undesirable or inappropriate behaviors can also be made more socially desirable. Consequently, sex role stereotypes might be diminished.

Finally, in line with a view of personality that emphasizes response capability, it may be important for individuals to *generate* responses when describing themselves, rather than simply endorsing items presented to them. Turner and Gilliland (in press) found that self-generated trait descriptions significantly predicted both typical and maximal laboratory dominance behavior in college men and women. Those individuals describing themselves as dominant expressed the most dominance and those describing themselves as reserved the least, whereas those not using adjectives on the dominance dimension fell in between. No information was available on the psychological masculinity or femininity of the subjects. Since it is now clear that both dimensions can coexist within the same individual (e.g., Spence et al., 1974), it would seem appropriate to examine whether these traits interact with typical and maximal situations.

The Present Study

This study examined the effects of psychological masculinity and femininity and sex role demands on the typical and maximal expression of dominance in women. Self-generated trait descriptions and self-reports of dominance were obtained from four groups of women: undifferentiated (low masculine, low feminine), feminine (low masculine, high feminine), masculine (high masculine, low feminine), and androgynous (high masculine, high feminine). These women then participated in two laboratory paradigms designed to assess their typical and maximal dominance behavior. Within these paradigms, the women were exposed to either male or female confederates. From the studies by Bem (1975) and Bem, Martyna, and Watson (1976), it was expected that feminine and undifferentiated women would have lower scores on a self-report dominance measure and would express less dominance in the typical laboratory situation than would masculine and androgynous women. Following Megargee's (1969) findings, it was predicted that women would express less dominance with male confederates than with female confederates in the typical laboratory situation. From Turner and Gilliland's (in press) study, it was expected that self-descriptive trait lists would predict dominance expression in both laboratory situations. It was expected that women who listed adjectives on the dominance dimension as self-descriptors (e.g., dominant, reserved) would be more extreme in dominance expressions than women who did not do so.

Although no specific predictions were made for the maximal laboratory situation, several general questions were proposed for investigation: How would feminine and undifferentiated women, compared to androgynous and masculine women, respond when dominance is made explicitly salient and desirable (maximal laboratory)? Would women respond differently to male and female confederates in the maximal laboratory? Would they express more dominance with the female confederates, as hypothesized for the typical laboratory?

Method

Design and Overview

The basic design was a 4 × 2 × 2 factorial with two between-subjects variables and one within-subjects variable. One hundred and twelve women were recruited as representatives of four combinations of psychological masculinity and femininity based on their scores on the short form of the Personal Attributes Questionnaire (PAQ; Spence & Helmreich, 1978). The women completed a variety of self-report measures and then each participated with two pairs of same-sex confederates in two group problem-solving situations designed to assess her typical and maximal dominance expression. Half of the women in each of the four groups were exposed only to male confederates and half only to female confederates.

Subjects

Several weeks prior to the beginning of the experiment proper, the short form of the PAQ was administered to 635 female introductory psychology students at the University of Texas at Austin. Using norms established by Spence and Helmreich (1978), the women were classified into four groups based on median splits on their PAQ masculinity (M) and femininity (F) scores: undifferentiated (low M, low F), feminine (low M, high F), masculine (high M, low F), and androgynous (high M, high F). The total pretesting sample was comparable to Spence and Helmreich's sample in mean PAQ scores, percentage of students falling into each M and F group, and relationship among the PAQ scales.

A total of 123 women were recruited for the present study from eligibility lists for the four M and F groups. Eleven women were dropped from the experiment: 3 because of suspicion, 3 because of equipment failure, and 5 because they failed to appear for their appointments. Half of the 28 women in each M and F group were randomly assigned to one of the two sex-of-confederates conditions. The experimenter and the confederates were blind with respect to the women's classifications. Each subject received course credit for participation in the experiment.

Measures

Personal Attributes Questionnaire. The PAQ is a measure of psychological masculinity and femininity developed by Spence et al. (1974). The short version of the PAQ (Spence & Helmreich, 1978) consists of 24 bipolar items belonging to three scales: masculine (M), feminine (F), and masculine–feminine (M–F). Correlations between the scales of the short version and the original 55-item PAQ are .93 (M), .93 (F), and .91 (M–F) for college students. For each item, the women were asked to rate themselves on a 5-point scale, with the endpoints having verbal labels. Items were scored from 0 to 4, with M and M–F items keyed in a "masculine" direction and F items keyed in a "feminine" direction. The 8 item scores for each scale were summed to give M, F, and M–F scores for each person. Some examples of PAQ items are "not at all independent – very independent" (M), "not at all emotional – very emotional" (F), and "very submissive – very dominant" (M–F).

Dominance scale of the California Psychological Inventory. The CPI Dominance scale (Gough, 1956) consists of 46 items pertaining to dominance in a "true–false" format, such as "I doubt whether I would make a good leader" (false) and "I think I would enjoy having authority over other people" (true). The total score for each person was obtained by summing the number of items responded to in the significant direction.

Person Description Form. This form (adapted from Turner & Gilliland, in press) is an idiographic assessment technique calling for the generation of a series of self-descriptive adjectives. Instructions are to "list the adjectives or traits that best describe you and your personality."

Following the procedure used by Turner and Gilliland, the women were classified into four groups via their responses, based on the taxonomy developed by Layman and McDonald (*The Layman–McDonald Trait Taxonomy: Round II;* cited in Turner & Gilliland, in press). The fourth group was added by the present investigators for exploratory reasons. Disagreements on categorization were resolved by discussion.

1. Dominant group—women listing traits categorized as autocratic/domineering (Layman–McDonald Dimension #7) or self-assertive (Dimension #20).
2. Reserved group—women listing traits on the opposite poles of these dimensions (e.g., democratic, reticent).
3. Trait irrelevant group—women not listing traits on these dimensions.
4. Mixed group—women listing traits on both the dominance and reserved dimensions.

Laboratory Measures

Two methods were used to assess dominance behavior in the laboratory (Turner, 1978).

Dominance rating. The *contents* of the subject's verbalizations (i.e., forceful, assertive statements) were independently rated by the two confederates as soon as she left the room. These ratings were made according to the following rationally constructed scale (adapted from Turner, 1978):

1. No dominance statements—totally passive.
2. Statements of a general nature (comments, statements of fact, clarifying statements); a few very weak opinions voiced with little conviction of involvement.
3. A few opinions offered; no disagreements with others expressed. May agree with others' opinions.
4. Opinions offered but no attempt to lead group (or very weak one); disagreements subtle and nondirect. Might offer suggestions about organizing.

5. Opinions offered with attempts to get some agreement from others; somewhat persuasive efforts toward other members. Statements solicitous to support, such as "Don't you think. . . . ?" An organizer —democratic—asks what others think (How do you feel? How about . . . ? What do you think?).

6. Strong attempts to persuade others and open disagreement with others. Emphatic statements, such as "I think. . . ." Person may take a while to warm up but takes over eventually. Assertive about opinions; leads; not too concerned about what others think.

7. Complete usurpation of leadership of group with insistence upon influencing conclusions of group. Usurpation of leadership from the *beginning. Strong* opinions; not democratic; very persuasive; strong disagreements.

The two confederates' ratings were summed together to yield a composite dominance rating for the typical laboratory and one for the maximal laboratory for each subject. Intraclass interrater reliabilities were .96 for the typical laboratory and .95 for the maximal laboratory.

Prior to the experiment proper, all confederates (five men and five women) participated in a series of laboratory training sessions to familiarize themselves with their roles and with the dominance rating scale. They practiced in different-sex as well as same-sex pairs with 20 pilot subjects. Tapes of the sessions were reviewed and discussed to promote consistency in their ratings.

The dominance rating sheet also included a 5-point scale for *facial* attractiveness, ranging from (1) very low to (5) very high, on which each subject was independently rated by the confederates. The confederates used an idealized *Vogue* model as a standard for these ratings. The summed ratings of the four confederates (two from each laboratory) served as a facial attractiveness score for each subject. Although the agreement among the raters on this measure was rather low (intraclass reliability = .47), the reliability of the average of the four raters was substantially higher (.78), suggesting moderate reliability for the overall attractiveness rating of each subject.

Talking time. The second method of assessing typical and maximal dominance in the laboratory was to measure the *amount* of verbalization, that is, the extent to which the subject monopolized the conversation. This was obtained from tape recordings of the laboratory sessions. Two confederates independently reviewed the tapes to determine percentage of talking time during the problem-solving period in the typical laboratory and in the maximal laboratory for each subject. Confederates' times were within 12 sec of each other for all of the tapes. Since it was expected that the groups would differ in the time needed to make final decisions, the problem-solving period was defined as "the time between the exit of the experimenter and the group's agreement upon the last of the four choices required by both the typical and maximal laboratory situations" (Turner, 1978, p. 124). Talking times were unavailable for five subjects in the typical laboratory because of equipment failure. The correlation between dominance rating and talking time in the typical laboratory was .58; the corresponding correlation in the maximal laboratory was .56. These relationships were consistent for subjects with male and female confederates. Turner (1978) combined talking time and dominance rating to form composite measures of typical and maximal laboratory dominance. This was not done in the present study because of the different effect of sex of confederates on these measures, reported in the Results section.

Evaluation of Group Members Form. This measure consists of a series of 5-point scales on which each subject was asked to rate herself and the two other group members (confederates) on leadership ability and passiveness/dominance. The subject completed one of these forms after each laboratory condition, thus providing self-ratings of typical and maximal laboratory dominance behavior. For the typical laboratory, self-rating correlated .55 with confederates' dominance rating and .52 with talking time. Corresponding correlations for the maximal laboratory were .31 and .37.

Procedure

The women signed up for one of four available sessions to complete the PAQ, the Person Description Form (PDF), and the CPI Dominance scale.

After completing these tasks, the women signed up for individual laboratory sessions, held 1 to 4 weeks later.[1]

Ten senior psychology students (five men and five women) rotated through the experimenter and confederates roles in the typical and maximal laboratory situations.[2] Subjects were exposed to either a female experimenter and four female confederates or a male experimenter and four male confederates during the laboratory session.

The subject was greeted by the experimenter, who explained that the other students participating in the session were already present. The other students were two confederates. One confederate was waiting in the lounge while the other was in the laboratory in order to surreptitiously turn on a concealed tape recorder. The experimenter entered the laboratory with the subject and the confederate, introduced everyone by his or her first name and had them sit around a table. They were then read the following:

This research is concerned with problem solving. The kinds of problems that we are interested in are

---

[1] Two subjects went to the laboratory session within 3 days of the paper-and-pencil session.

[2] The authors gratefully acknowledge the laboratory assistance of Lisa Fowler, Bill Aven, Charlene Henslee, Steve Bates, Teresa Matthews, Mike Dickey, Nancy Feinberg, Adele Goldstein, Paul Burnham, and Ray Mechler.

often abstract and seem to have no clear-cut answer. However, we are interested in what people's conclusions concerning these problems are and how they arrived at them. I will read the problem to you and then give you 10 minutes to come up with your conclusions as a group. You may have seen problems similar to this before.

The school district in a small community is in financial difficulty. The school board must dismiss eight faculty members in addition to other cutbacks in order to have enough money to complete the school year. A decision has already been made that the eight faculty members would be specialists in various areas, not teachers of the basic subject areas. Which four of those listed below would you choose to remain?

1. Reading specialist
2. Counselor
3. Assistant football coach
4. Special education teacher in math
5. Assistant band director
6. Drama teacher
7. Diagnostician of learning disabilities
8. Teacher of accelerated English classes
9. Teacher of accelerated math classes
10. Baseball coach
11. Work–study supervisor
12. Art teacher

The experimenter then placed a description of the problem in the middle of the table along with a pencil and a group conclusion form, on which someone was to write down the four persons of the group's choice. The experimenter reminded the group of the 10-minute time limit, pointed out the clock on the table, and left the room.

The confederates' behavior was primarily composed of presenting both pro and con arguments as to which specialists should be dismissed. Although they interacted freely in the discussion, they were democratic in their approach and only moderately assertive. Within this general pattern, three other procedures were followed:

1. At initiation points (i.e., when the experimenter left and returned) the confederates gave the subject 3–4 seconds to begin the interaction, if she chose to do so.

2. Approximately halfway through the session, one of the confederates began to discourse on a tangential topic. This lasted for 1 minute unless it was terminated by the subject.

3. At some point during the 10 minutes, one of the confederates openly disagreed with one of the subject's statements to determine her reaction to this challenge.

After 10 minutes the experimenter returned, and if the group had not yet finished the task, they were given an additional minute. All of the groups finished within 12 minutes' total time. The experimenter talked briefly about the problem and collected the group conclusion form. The experimenter then told the group that it was necessary to get their individual reactions to the group process and asked the subject to come to an adjacent room, saying that he (she) would return to get the others' reactions after talking to the subject. The subject then completed an evaluation of group members form. During this time, the confederates independently rated the subject on dominance and facial attractiveness.

The subject was then read the following statement:

> For the second part of this research, you will be with another group of people solving a problem similar to the one you worked on here. In this group, I want you to try to be the leader. I want you to be as dominant and assertive as you can be. This is an ability test. We will tape-record this session so that we can see how well you do. Remember, this is a dominance ability test. You are to see that your group comes up with satisfactory answers to the problem.

The experimenter then stated that the other students (confederates) in this part of the experiment were ready to begin and led the subject to the second laboratory while stressing the ability nature of the assessment.

The maximal laboratory situation was similar to the typical situation. Again, one confederate was waiting in the lounge while the other was in the laboratory to turn on the tape recorder. After following the same introductory procedure as enacted in the typical situation, the experimenter read the following:

> This research is concerned with problem solving. The kinds of problems that we are interested in are often abstract and seem to have no clear-cut answer. However, we are interested in what people's conclusions concerning these problems are and how they arrived at them. I will read the problem to you and then give you 10 minutes to come up with your conclusions as a group. You may have seen problems similar to this before.
>
> Imagine that our country is under threat of imminent nuclear attack. A man approaches you and asks you to make an independent decision: There is a fallout shelter nearby that can accommodate 4 people but there are 12 people vying to get in. Which 4 do you choose to go into the shelter? Here is all the information we have about the 12 people:
>
> 1. A 40-year-old male violinist who is a suspected narcotics pusher.
> 2. A 34-year-old male architect who is thought to be a homosexual.
> 3. A 26-year-old lawyer.
> 4. The lawyer's 24-year-old wife who has just gotten out of a mental institution.
> 5. A 75-year-old priest.
> 6. A 34-year-old retired prostitute who was so successful that she's been living off her annuities for 5 years.
> 7. A 20-year old black militant.
> 8. A 23-year-old female graduate student who speaks publicly on the virtues of chastity.

9. A 28-year-old male who will only come into the shelter if he can bring his gun with him.
10. A 12-year-old girl who has a low IQ.
11. A 30-year-old MD who is an avowed bigot.
12. A high school student.

The experimenter followed the same procedure as before and left the room. The confederates' behavior during the problem-solving period was the same as that of the confederates in the typical laboratory.

After 10 minutes, the experimenter returned and the same procedure as outlined above was followed, with the subject filling out another evaluation of group members form. The subject was then debriefed and was asked not to discuss the experiment with anyone until the study was completed.

The school board and bomb shelter paradigms were counterbalanced for the typical and maximal laboratory conditions. Since preliminary analyses did not reveal a significant order effect or a significant difference between the two paradigms across laboratory conditions, it was assumed that the two paradigms were equivalent.

Results

As expected, mean scores on the CPI Dominance scale differed significantly by M and F group, $F(3, 108) = 6.41$, $p < .001$. A planned comparisons [3] revealed that, as predicted, the means of the undifferentiated and feminine women (27.3 and 26.9) were significantly lower than the means of the masculine and androgynous women (32.1 and 32.7), $F(1, 108) = 19.04$, $p < .01$. This difference is entirely due to the correlation of .49 ($p < .01$) between the PAQ M scale and the CPI Dominance scale; the F scale has no relationship to CPI dominance ($r = .00$).

Table 1 presents the means and standard deviations of the laboratory measures by M and F group and sex of confederates. Results were analyzed by the three-way analysis of variance (M and F Groups × Sex of Confederates × Laboratory Condition) presented in Table 2. The difference between typical and maximal measures was highly significant for dominance rating ($p < .001$) and talking time ($p < .001$), showing that the maximal instructions were highly effective in eliciting more dominance behavior in the second laboratory situation.

As anticipated, M and F group had a significant effect on dominance rating ($p < .002$) and talking time ($p < .01$). For dominance rating, planned comparisons showed a significant difference between the means of the undifferentiated and feminine women and those of the masculine and androgynous women for the typical laboratory, $F(1, 208) = 9.82$, $p < .01$, and for the maximal laboratory, $F(1, 208) = 7.75$, $p < .01$.

For talking time, results of planned comparisons were parallel: significant for the typical laboratory, $F(1, 198) = 9.86$, $p < .01$, and marginally significant for the maximal laboratory, $F(1, 198) = 3.47$, $p < .07$.

Closer examination of Table 1 showed that the means of the four M and F groups tended to follow a consistent pattern: masculine, androgynous, undifferentiated, and feminine, with the masculine women having the highest dominance ratings and the feminine women the lowest.

Sex Role Behavior

The effect of sex of confederates on women's dominance behavior is complex. The prediction that women would express less dominance with male confederates than with female confederates in the typical laboratory was supported for dominance rating, but contradictory results were obtained for talking time.

Although for dominance rating the main effect for sex of confederates was nonsignificant (Table 2), the interaction between sex of confederates and laboratory was significant ($p < .03$). Planned comparisons showed that for the typical laboratory, the means of women with male and female confederates were significantly different, $F(1, 208) = 4.38$, $p < .05$, whereas for the maximal laboratory, the means were practically identical, $F(1, 208) = .02$, *ns*. Thus, for dominance rating, women's behavior was not consistent in the two laboratory situations. The women were significantly less dominant with male confederates in the typical laboratory, as predicted, but equally dominant with male and female confederates in the maximal laboratory.

[3] Planned comparisons among cell means were performed according to procedures described by Keppel (1973; pp. 445–446).

significant for the maximal laboratory, $F(1, 198) = 8.19$, $p < .01$.

Self-Rating of Laboratory Behavior

Unlike findings for dominance rating and talking time, self-ratings of the M and F groups do not follow a consistent pattern. The main effects for M and F group and sex of confederates were not significant, $F(3, 104) = 1.49$, *ns*, and $F(1, 104) = 1.39$, *ns*, respectively. Overall, the women did not perceive themselves as less dominant with male than female confederates.

Facial Attractiveness

For the facial attractiveness measure, the main effect for sex of confederates was nonsignificant, $F(1, 103) = 1.63$, *ns*, indicating that the male and female confederates perceived the women in their respective groups as equally attractive. Differences among the M and F groups were unremarkable, and the effect of M and F group on facial attractiveness was nonsignificant, $F(3, 103) = .21$, *ns*. Facial attractiveness, however, correlated significantly with both typical and maximal talking time ($r = .32$; $r = .21$) and typical and maximal dominance ratings ($r = .30$; $r = .22$); sex of confederates did not affect these correlations.

Self-Generated Trait Descriptions

As expected, trait group significantly predicted women's self-reports on the CPI Dominance scale, $F(3, 108) = 10.96$, $p < .001$, and their behavior in the laboratory situations; dominance rating, $F(3, 104) = 5.67$, $p < .001$; talking time, $F(3, 99) = 5.86$, $p < .001$. For all of these measures, the means of the trait-irrelevant group fell between those of the dominant and reserved groups. The mixed group behaved similarly to the trait-irrelevant group in the typical laboratory and the reserved group in the maximal laboratory. Results for self-rating of laboratory behavior were consistent with those for dominance rating and talking time. Trait group had a significant effect on this measure, $F(3, 104) = 4.34$, $p < .007$. For both laboratory situations, women in the dominant group perceived themselves as the most dominant, followed by women in the trait-irrelevant, mixed, and reserved groups, respectively.

Trait group had a borderline significant effect on the facial attractiveness measure, $F(3, 107) = 4.36$, $p < .06$. The facial attractiveness of the trait-irrelevant and dominant groups were similar and both were significantly greater than that of the reserved group. Post hoc comparisons showed that the differences between these groups were significant: trait irrelevant versus reserved, $F(1, 107) = 6.41$, $p < .05$; dominant versus reserved, $F(1, 107) = 11.54$, $p < .01$.

Multiple Regression Analysis

To get an idea of the relative contributions of the independent variables to the laboratory dominance scores, five predictors were entered into a multiple regression in a hierarchical sequence, CPI Dominance, M and F group (coded as three dummy variables), trait group classification (also coded as three dummies), sex of confederates, and facial attractiveness. The outcomes to be predicted were typical and maximal laboratory dominance and talking times.

CPI Dominance was entered first to see if M and F group contributed unique variance to the laboratory criteria beyond that predicted by CPI Dominance and because the laboratory outcomes could reasonably be regarded as validity criteria for the CPI scale itself.

Results of the multiple regression analysis are shown in Table 3. It is apparent the CPI Dominance accounts for the greatest amount of variance in the laboratory outcomes, and in only one instance (maximal dominance rating) did the M and F classification significantly contribute to variance beyond that contributed by the CPI scale. Facial attractiveness and sex of confederates both made significant contributions to the outcomes in the typical laboratory, and sex of confederates also contributed significantly to talking time in the maximal laboratory.

Although the trait group classification pro-

*$p < .05$.

vided no additional information in the multiple regression, it should be noted that the correlation between CPI Dominance and the dominant trait group dummy was $r = .42$, ($p < .01$), with the reserved group, $r = -.39$ ($p < .10$), and with the trait-irrelevant groups, $r = .00$. This is important because it suggests a moderate amount of multicolinearity for two of the dummy variables, which reduces the potential predictiveness of trait group classification in this analysis.

In another hierarchical analysis, M and F classification was entered first and CPI Dominance entered second. In every instance, M and F group accounted for a significant proportion of the variance (ranging from 5% to 13%, average = 8.6%). However, the contribution of CPI Dominance was also always significant (range from 5% to 14%, average = 11.5%).

The results of these analyses indicate that the fourfold M and F classification did not regularly provide additional information beyond that given by CPI Dominance scores. This interpretation cannot be readily generalized, however, since the outcome criteria in this particular study could be regarded as exemplars of the CPI scale itself. In studies with other behavior outcomes, the pattern of results might be different.

Despite these findings from the multiple regression, useful information on women's dominance expression would not have come to light without the perspective of psychological masculinity and femininity, which conceptually guided this study. The consistent pattern observed for the four M and F groups in both laboratory situations for both dependent variables (masculine > androgynous > undifferentiated > feminine) could not be explained solely by the relationship between CPI Dominance and the PAQ M and F scales. For example, since the CPI scale is significantly related to the M scale ($r = .49$, $p < .01$) and unrelated to the F scale ($r = .00$), why did the masculine women consistently express more dominance than the androgynous women when the latter actually had slightly higher CPI Dominance scores (32.7 vs. 32.1) and M scores (24.1 vs. 23.6)? With male confederates, masculine women obtained significantly higher dominance ratings than the androgynous women in the maximal situation ($p < .01$) and marginally significantly higher ratings in the typical situation ($p < .10$). Apparently, psychological "type" had an effect on women's dominance behavior beyond that predicted from CPI Dominance and PAQ scale scores.

Discussion

Sex role demands were an inhibitory force in the typical laboratory, where women either consciously or unconsciously suppressed their dominance behavior with men, but not in the maximal laboratory, where women were equally dominant with men and women. The latter gave us the opportunity to observe how women would behave in a situation in which

dominance, a stereotypically "masculine" behavior, was made salient and socially desirable. Apparently, women have the capacity to express relatively more dominance than they generally do under typical or everyday circumstances calling for appropriate sex role behavior. The explicit instructions to be maximally dominant seemed to serve as a "green light" for the women to ignore established norms. The women were actually capable of behaving in a dominant fashion with men but typically inhibited this behavior. These results demonstrate the importance of distinguishing between what individuals do and what they can do. Despite reserved or submissive behavior under typical conditions, many individuals are capable of displaying dominant behavior.

Findings for laboratory talking time were the reverse of expectations. Women were significantly more talkative with male confederates than with female confederates in both laboratory conditions. In retrospect, this finding is hardly surprising. Women may have been more "turned on" by participating in an experiment with men. Although talking time showed substantial relationships with other dominance measures (e.g., CPI Dominance scale; dominance rating), it is by no means a "pure" measure of dominance. Verbal behavior undoubtedly contains components of sociability, and just as dominance behavior has a negative valence in terms of traditional sex role standards for women, sociable behavior, particularly with the opposite sex, has a positive valence. Thus, sex role expectations were actually conducive to verbal interaction with men in the present study.

We believe that mean dominance rating differences as a function of the rater's sex are valid and not due to rating artifacts. Male and female confederates were trained together in pilot work, and raters' sex was significant only under typical instructions. Also, masculine women rated by males in the typical laboratory obtained higher dominance ratings than did the other three M and F groups rated by female confederates. In addition, correlations between talking time and laboratory dominance ratings were virtually identical regardless of whether males or females did the dominance ratings. And finally, correlations of CPI Dominance with laboratory dominance did not differ significantly as a function of sex of confederate ($r = .30$ with female confederates; $r = .49$ with male confederates).

These findings have several important implications. First, traditional sex role prescriptions have an impact on women's behavior. They can serve as facilitators or inhibitors depending on situational context. Second, women's capabilities for opposite sex role related behaviors may be underestimated. Women tend to suppress certain dispositional inclinations when sex role demands are operating but can exhibit them when these demands are no longer salient. Finally, it is possible to remove inhibitory forces in the environment so that women can express dominance more freely.

On the other hand, consistent individual differences were observed in the enactment of sex roles. Psychological masculinity and femininity, as measured by the PAQ, had a significant impact on women's self-reports and behavior even when they were given explicit instructions to be as dominant as possible. These findings are consistent with those reported by Bem and her coworkers (Bem, 1975; Bem et al., 1976).

Additionally, these psychological variables seemed to influence the degree to which women responded to the situational sex role demands, that is, masculine women showed the least difference in behavior as a function of confederates' sex in the typical laboratory. It is noteworthy that feminine women showed little increase in dominance when moving to the maximal laboratory with female confederates but showed a large increase with male confederates. Whether this is due to the feminine women being more influenced by the sex of the experimenter giving the maximal instructions or to less motivation in these women to express their dominance capabilities in the context of other women is unclear (see Eagly, 1978). That feminine and undifferentiated women showed less dominance than masculine women in the maximal laboratory suggests, contrary to Bem's (1975) conclusions, that they may be somewhat lacking

in basic competence and not simply inhibiting stereotypically masculine behavior. To study the nature of masculinity and femininity, therefore, researchers need to distinguish conceptually between sex role behaviors and psychological dimensions of masculinity and femininity as advocated by Spence & Helmreich (1978), especially if they are attempting to predict sex role related behaviors.

Another finding consistent with Spence and Helmreich's (1978) formulations concerns facial attractiveness. Undifferentiated, feminine, masculine, and androgynous women were rated as *equally* attractive by the confederates. These results contradict popular notions that masculine women are physically unattractive. Interestingly, although facial attractiveness was independent of psychological masculinity and femininity, this variable was significantly related to dominance behavior in the laboratory. In the typical laboratory, facial attractiveness accounted for 14% of the explained variance.

Many of our commonly held notions about psychological differences between the sexes are based on observations of behavior in everyday situations eliciting sex role behavior. The notion that women are less dominant than men may reflect adherence to traditional sex role standards and expectations more than strong psychological differences. Women may be more similar to men in psychological makeup than is generally assumed. Perhaps research paradigms utilizing a response capability approach will shed new light on psychological differences between the sexes. Unfortunately, this investigation did not have a male sample for purposes of comparison.

Results for the self-generated trait descriptions were as anticipated and similar to those reported by Turner and Gilliland (in press). These descriptions are predictively valid measures and refer to relatively consistent dispositional and behavioral variables. Unlike traditional personality measures, which require people to respond to a specific set of stimuli chosen by the experimenter, self-generated descriptions enable people to report what *they* perceive as relevant to their personalities. Bem and Allen (1974) argue that a more idiographic approach to assessment would improve the predictive validity of personality tests. Further, they point out that "there is no inherent conflict between an idiographic approach to assessment and a nomothetic science of personality" (p. 511). Results of the present study and Turner and Gilliland's study show that an idiographic assessment technique can significantly predict dominance behavior.

The behavior of the dominant, reserved, and trait-irrelevant groups is of particular interest in light of Bem and Allen's (1974) formulations. Women who perceived the dominance dimension as relevant to their personalities (i.e., dominant and reserved groups) were extreme in their dominance expression in accordance with their self-descriptions, whereas women who perceived this dimension as unimportant (i.e., trait-irrelevant group) were moderate in their dominance expression. The mixed group was inconsistent in the pattern of responses. This trait, then, was not of equal importance to all of the women, and this had a significant impact on their behavior. The predictive validity of personality measures may well be improved by focusing on those individuals who perceive the trait under consideration as relevant to their psychological makeup.

Finally, one must come away impressed with the strength of the CPI Dominance scale as a potent predictor of dominance behavior in the laboratory. The multiple regression analysis showed that this scale explained an average of 75% of the total variance accounted for by all predictors. The lesson to be learned from this finding is that in studies of psychological masculinity and femininity employing traditional aspects of dominance behavior as a criterion, one needs to be concerned with the *unique* contributions that these concepts make to outcomes beyond that given by traditional psychological measures. Although the concepts of psychological masculinity and femininity can be regarded as theoretically more valuable than the traditional concept of dominance, recognition of this close alliance allows one to make contact with an already established literature of research findings whose origins lie in a different conceptual framework.

Effects of Person Salience Versus Role Salience on Reward Allocation in a Dyad

Elena M. Carles and Charles S. Carver
University of Miami

Previous research shows that resource allocation in a dyad sometimes follows the principle of equity (proportional reward) and sometimes that of parity (equal reward). Existing evidence does not clarify the conditions under which each of these rules is invoked, however. A number of theorists have suggested that salience of the other as a person should lead to parity-based allocation, whereas salience of the other as a functionary filling a role should lead to equity-based allocation. The present study tested these possibilities. Subjects were led to perceive their own inputs to group performance as being either substantially lower or substantially higher than a partner's inputs. The partner had been portrayed to the subject in terms that made salient the partner's personal characteristics, the partner's role assignment, or neither of these. Among females, subsequent reward allocation followed the predicted pattern in both high- and low-input conditions. Among males, contrary to expectation, person salience led to heightened feelings of competitiveness and to increased allocations to the self. Discussion centers on the theoretical implications of these findings.

When group members interact, each member gives something to the interaction and each takes something in return. These are the costs and the rewards of group interaction (Thibaut & Kelley, 1959). Although rules for apportioning a group's rewards are sometimes determined by some form of open bargaining (e.g., Morgan & Sawyer, 1967), members of a group often arrive at implicit allocation rules without direct feedback from each other.

When persons are required to allocate group resources between themselves and their partners in a dyad, the division can be accomplished in many different ways. One may act solely in self-interest, keeping all the resources for oneself; one may give all the resources to one's partner; or one may divide the resources, giving some percentage to oneself and some to one's partner. Research in this area, which is often termed "distributive justice," usually finds that the allocator chooses the latter, that is, some division between self and partner. The question, then, that is basic to that area of investigation is this: What characteristics of the group members, the context, or the ongoing interaction affect the allocator's decision as to how the resources will be divided?

Studies in this area typically formalize the interaction between group members as follows. The subject (future allocator) and the other member are given some cooperative task. The subject subsequently receives feedback as to the relative productivity (inputs) of the two members. The group then is supplied with some reward, usually monetary, and the subject is asked to allocate this reward (or in some cases, reallocate it after an initial distribution by the partner).

Allocation Rules

Equity. One rule that could be used to allocate the group's resources is the principle

This research was conceived and conducted as a doctoral dissertation by the first author, under the supervision of the second author.

of equity; that is, the notion that one should be rewarded in proportion to one's inputs. There is considerable evidence that this rule is often used in resource allocation. For example, Adams (1963) showed in a series of experiments that people tend to minimize the psychological differences between their inputs and their outcomes, in relation to the other members of a dyad.

Because many factors (e.g., psychological, social, physical) influence people's perceptions of inputs and outcomes, however, equity theory has been much modified since it was originally proposed. For example, Walster, Berscheid, and Walster (1973) postulated that there could be any number of systems of equity within a given social structure and that powerful individuals within that structure will attempt to induce others to accept systems beneficial to the group in power. According to this reasoning, group members can be influenced to believe that any method of apportionment is "equitable." Leventhal (1976) has also noted limitations of equity theory and has pointed out a number of other allocation rules that could be used instead of the equity rule.

Equity and parity. In spite of the multiple possibilities, however, a review of the literature indicates that available resources are usually distributed in one of two ways. In some cases the equity rule operates, and resources are distributed to each member of the dyad according to merit or observed performance in the prior task. In other cases, the resources are distributed *equally* between the members. This is called the rule of parity.

It is generally accepted that people choose one of these two rules as being appropriate in a given situation. Furthermore, it is clear that which rule appears appropriate in one set of circumstances does not necessarily dictate which is seen as appropriate in other circumstances (cf. Walster & Walster, 1975). Studies involving unequal input[1] have yielded some support for the equity solution (Leventhal & Anderson, 1970; Leventhal & Lane, 1970; Leventhal & Michaels, 1969) and some for the parity solution (Morgan & Sawyer, 1967; Wiggins, 1966). Apparently there is some additional factor that must account for this discrepancy between findings.

Degree of interaction. Shapiro (1975), in reviewing these studies, found that when equity predominated, there had been minimal social interaction between the allocator and the partner. In contrast, where parity occurred, there was either an acquaintance between the two or the implication of future interaction. Shapiro attempted to explore the possibility that the critical influence on resource allocation was the expectation of future interaction. He found, in a subsequent experiment, that when such an expectation existed, subjects were more likely to allocate resources according to parity; when no expectation existed, equity prevailed.

Shapiro's method, however, leaves serious questions as to exactly what variable determined his subjects' choice of allocation rule. In the condition involving no expectation of future interaction, so-called partners ostensibly participated in the study at completely different times. On the other hand, in the future-interaction condition the partners not only anticipated future interaction, but they worked in adjoining rooms with the door left open and could hear each other respond to questions. This confounding of the expectation of future interaction with a number of other variables prevents the ruling out of other potential causes as having determined subjects' choices of allocation rule.

Salience as person. Other theory suggests the possibility that Shapiro's effect actually depended on a different variable: the degree to which the partner was salient as a person. For example, Lerner (1977; see also Lerner, Miller, & Holmes, 1976) has theorized that the perceived relationship between partners should affect which rule of allocation is pre-

[1] Several researchers (Leventhal, Allen, & Kemelgor, 1969; Leventhal & Bergman, 1969; Leventhal, Weiss, & Long, 1969) have reported that when inputs are equal, subjects react to an unequal division of resources by reallocation to restore equity (equal pay for equal work). However, in the case of equal input (e.g., equal work), the equity solution (proportional allocation) happens also to be the parity solution (equal allocation). Thus comparative tests require that there be unequal inputs.

ferred. Lerner suggested that when one's partner is seen as similar to oneself, parity prevails. On the other hand, when "people relate to one another on the basis of their *position or function* in the cooperative endeavor . . . the justice of equity would be applied" (Lerner, 1977, p. 47, emphasis added). Thus as others are seen in terms of their functions (e.g., "co-worker") rather than as individuals, the rule for allocation of group resources should change from parity to equity. Deutsch (1975) has similarly suggested that seeing people in terms of their usefulness (function) leads to equity, whereas salience of social relations causes parity to dominate.

Low-input situations. Subjects in what might be regarded as personalizing circumstances often do allocate resources according to parity (Leventhal, Michaels, & Sanford, 1972; Shapiro, 1975). But there are special circumstances in which equity-type allocation has been found regardless of an implied relationship (Shapiro, 1975). Specifically, this has occurred when the subject's input was *less* than the partner's input. For the subject to invoke a parity rule in this case would mean, in effect, taking some of the other's earning for himself. This is not something that one would do to another "person" without his permission; nor is it the way one would be inclined to treat a "partner." It thus seems that the parity–equity decision discussed above may be most relevant to circumstances in which one's own contribution to the task had outweighed the other's input.

Present Study

It was suggested above that personalization of one's partner in a dyad may bias the choice of allocation rule toward parity, though this possibility has not yet been tested explicitly. Moreover, a review of the literature suggests that equity has prevailed when subjects were implicitly led to view their partners in terms of their roles. It seems plausible that an even greater bias toward an equity solution may occur if the other person is explicitly made salient as a functionary in a role. The present study examined these possibilities more closely.

In virtually all previous research, the relationship between the partners has been, either explicitly or implicitly, competitive. The "other person" in the present research similarly occupied what was implicitly a competitor role.[2] The present subjects experienced outcomes into which they themselves ostensibly had greater or lesser input than their "partners." The partner was portrayed to subjects such that (a) the partner's identity as a person was made salient, (b) the partner's role in the task was made salient, or (c) neither of these was made salient. The subject then was asked to allocate a group reward. It was expected that role salience would lead to equity-based allocation and that person salience would lead to parity-based allocation, both relative to the condition in which neither person nor role was salient. It was also expected that these tendencies would be maximized when the subject's perceived input was greater than the partner's.

Method

Subjects and Procedures

Subjects were 120 undergraduates (60 males and 60 females) from the University of Miami. One other subject was deleted because questioning revealed that he had not understood the experimental manipulation. Subjects were tested one at a time. Each was told, however, that he or she was participating as part of a (same-sexed) pair. The partner was ostensibly in a different experimental cubicle.

The experimenter explained that the study was intended to test the effects of group concentration on telepathic ability. The subject and his or her partner would be trying to receive telepathic communications

---

[2] There seems to be only one *non*competitive context in which roles are salient: when the roles are defined strictly in terms of cooperative partnership. If resource allocation becomes an issue in such a relationship, presumably both of the influences under consideration here—personalization and role salience—would influence allocation in the direction of parity, because sharing is a component of this role. It would thus be difficult to separate the two influences from each other. In part for this reason, the present research focuses on a relationship whose role characteristics should exert an influence opposite to that expected for personalization. It is likely that this implicitly competitive relationship corresponds relatively well in this respect to most relationships in which resource allocation is an issue.

from a sender.[3] The experimenter emphasized that success depended on concentration exerted by both subjects, and not on their specific abilities. Subjects were told that they would get feedback on the accuracy of both group members later on. The experimenter also stressed that partners would *not* meet either during or after the experiment. Ostensibly this was being arranged so that the partners would not be distracted by the anticipation of interacting. In reality, this information was being provided explicitly to remove anticipation of interaction as a possible cause of the behavioral effect under investigation. Thus the test of our hypothesis was not contaminated by this additional variable (cf. Shapiro, 1975).

Salience manipulations. In the person-salient condition, after the above task description had been given, the subject was told that distraction during the task would be minimized if the subject thought of the other as a unique individual. The experimenter ostensibly had been able to gather some personality information on potential participants from certain class sections. Subjects were told that although such information had not been obtained from them themselves, the information was available for their partner.[4] The subject then was given a brief description of the hypothetical partner, including the following specific information:

> Your corecipient's name is Pete (Linda), and he (she) is 19 years old. S/He lives in south Florida, and it says here that s/he's a Methodist.
>
> The personality tests show that Pete is mildly extraverted and somewhat impulsive. On a forced-choice questionnaire, Pete endorsed the item 'I often leap before I look, and that gets me into trouble sometimes.' The report indicates that Pete rarely feels depressed or anxious. He said 'I really enjoy life, and I don't let the bad things that happen get me down.'
>
> Pete prefers an active to a passive life. He participates in many sports, and says that he would rather play tennis on a Sunday afternoon than watch it on TV. Pete is highly sociable and loves to talk to people.
>
> Since Pete uses so much energy doing sports and socializing, it is not surprising that he reported himself to be somewhat slack in getting his school-work done, and leaves everything till the last minute.

The emphasis of all the information was to "personalize" the partner as much as possible, but to do so in such a way that the partner would be fairly representative of students at the University of Miami.

In the role-salient condition, the subject was told that thinking about who his or her counterpart might be would be disruptive. If the subject must think about the other at all, he or she should think of the role that the other plays as a receiver of telepathic communications.

Control subjects were told that the study was to test the effects of a specific vitamin complex on concentration and success in ESP tasks. Subjects were told that they were in a control group that would receive no vitamin. Although subjects were told that they would be working with a partner who was in another room and who would be concentrating on the same task, the partner was not emphasized either as an individual or as a role. The intent behind these instructions was to give the subject an orientation to the task in which neither person nor role would be salient.

In all experimental conditions, subjects were told to do their best and were reminded that the other person would also be trying to do his or her best at the task.

Input manipulation. Each subject then was asked to work on the ESP task. On each trial, the subject attempted to guess (when a signal light went on) which ESP card an experimenter was holding, from among four possibilities. After the task was completed, the subject was given false feedback as to the number of correct guesses made by each individual of the alleged pair. The subject was told that he or she had performed either substantially better than the partner (6 correct for the subject vs. 2 correct for the partner) or substantially worse than the partner (2 correct for the subject vs. 6 correct for the partner).

Dependent measure. The subject was then told that a small grant had enabled the experimenter to be able to reward the group's effort. Each group ostensibly was being rewarded according to how well the group had performed. After checking the group's total of "correct" responses, the experimenter indicated that the subject's group would be awarded four dollars. The subjects were told that they had been chosen by lot to divide the earnings between their partner and themselves. The experimenter said that how to divide the money was entirely up to the subject. The partner implicitly did not know what the group's total monetary reward would be,

---

[3] This cover story was chosen because it allowed easy manipulation of perceived input and because it allowed the roles held by the subject and "co-subject" to be equivalent to each other in terms of nature of function performed, status, and so forth. Doubts as to the credibility of the cover story among subjects proved to be unfounded, as assessed by pilot testing. Indeed, many subjects expressed some disappointment upon learning that the study had not actually concerned telepathy.

[4] This statement was included to guard against the possibility that subjects' behavior might be influenced by being "known" by the other. The effects of the study thus depended solely on the subjects' perceptions of the cosubject, rather than concern over the cosubjects' knowledge of the subjects.

and the subject was told that the division would be completely anonymous, even to the experimenter. Thus the subject should have perceived complete freedom in allocating resources.

The subject was left alone in the cubicle to fill out a form indicating what amount should go to himself or herself and what amount to the partner. The subject sealed this form (coded only by a special number) in a envelope and placed it in a depository, from which a departmental secretary ostensibly would take it later to type checks to be mailed out. As soon as this secret division of earnings was completed, the subject was given a postexperimental questionnaire and was debriefed. No subject actually received money. All were debriefed immediately in that regard, and were provided with an opportunity to vent any negative feelings that the deception had caused. In general, subjects had little negative reaction, feeling that the small amount of money involved did not warrant being upset at its loss.

Results

In the interest of clarity, we will present the behavioral results of the study first, and then the results of the various manipulation checks.

Allocation of Resources

A 3 (Role-Salient vs. Person-Salient vs. Control) × 2 (High vs. Low Input) × 2 (Male vs. Female) analysis of variance of subjects' dollar allocations to themselves revealed three significant effects. First, there was a large effect for input level, $F(1, 108) = 34.23$, $p < .001$, indicating that subjects who were told that they had done better in the task than their cosubject (high input) allocated more money to themselves than those who were told they did more poorly than their cosubject (low input). There was also a significant main effect for sex, $F(1, 108) = 11.71$, $p < .001$, such that males allocated more earnings to themselves than did females. Of greatest interest was a highly significant interaction between relationship and sex of subject, $F(2, 108) = 9.38$, $p < .001$ (see Figure 1). This interaction indicated that subjects' allocations were indeed influenced by their relationships to their partners, but the nature of that influence differed dramatically between males and females. As is clear from Figure 1, each gender's behavior was consistent across the two levels of perceived input.

A Duncan multiple range test indicated that females (combined across input levels) allocated significantly more to themselves in the role-salient than in the person-salient condition ($p < .05$). The control mean did not differ reliably from either the person mean or the role mean but fell approximately

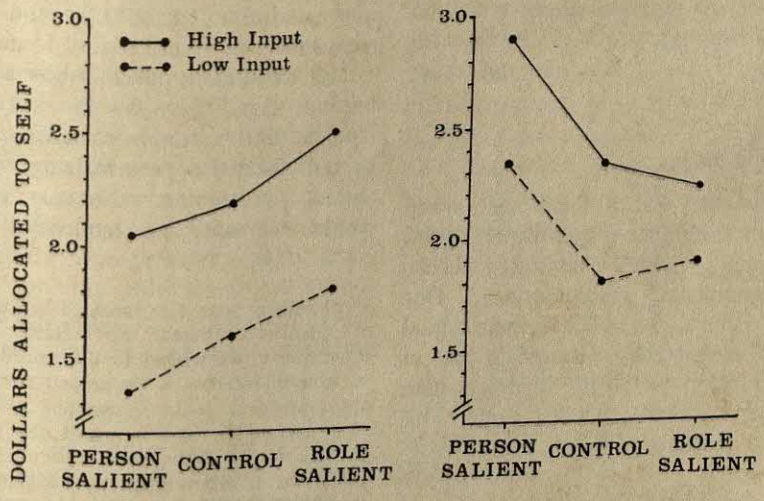

Figure 1. Mean allocation to self, in dollars, by (a) females and (b) males in each of three relationship conditions.

Table 1
Mean Ratings of Perceived Uniqueness of Cosubject, Knowledge of Cosubject, Degree to Which Cosubject Was Like Oneself, and Felt Competitiveness Toward Cosubject

Item	Relationship		
	Person	Control	Role
Uniqueness of cosubject			
Males	3.25	2.60	2.20
Females	3.80	2.75	2.00
Knowledge of cosubject			
Males	2.65	1.95	1.50
Females	3.30	1.50	1.20
Similarity to self			
Males	4.80	3.90	4.90
Females	5.35	5.05	3.80
Felt competitiveness			
Males	3.25	2.00	1.85
Females	1.60	1.90	2.75

Note. Group $n = 20$.

midway between them. These findings, among females, were precisely as had been predicted.

The findings for males, on the other hand, took a form opposite to the prediction. That is, when combined across input levels, males allocated to themselves more of the group's earnings in the person-salient condition than they did in either the role-salient condition or the control condition ($ps < .05$ by Duncan test). The latter two means did not differ reliably from each other.

Manipulation Checks

Degree of input. Subjects had been asked to respond to a number of postexperimental questions, some of which constituted checks on the experimental manipulations.[5] One item asked subjects to indicate their actual performance in the task compared to that of the ostensible cosubject, with three response options: higher, lower, and the same. This item served as a check on the input manipulation. All subjects retained for data analysis answered correctly for their input levels.[6]

Nature of relationship. Four questions indirectly assessed the way subjects perceived their cosubjects. These can be construed as checks on the relationship manipulation. Separate analyses of variance compared subjects' responses (on 7-point scales with suitable anchoring phrases) on each of these postexperimental questions.

The first item asked subjects to what degree they perceived the other as a unique individual. It was expected that this tendency would be increased by the person manipulation and decreased by the role manipulation. Consistent with this expectation, analysis of responses to this item revealed a significant main effect for relationship, $F(2, 108) = 6.72$, $p < .005$ (see Table 1). A Duncan multiple range test showed that when data were combined across both input and gender variables, subjects in the person condition perceived the other as a unique individual more consistently than did subjects in either the role or the control condition ($ps < .05$).

A second item asked subjects how much they knew about the other. It was anticipated that the personalizing manipulation should increase this tendency. As expected, an analysis of variance showed only a highly significant main effect for relationship, $F(2, 108) = 18.89$, $p < .001$ (see Table 1). A Duncan multiple range test showed that, overall, subjects in the person condition indicated significantly more knowledge about the cosubject than did subjects in either the control or the role condition ($ps < .05$); the latter two means did not differ reliably from each other.

The third item asked subjects to indicate to what degree they saw the other as another student like themselves. Again, it was expected that the personalizing manipulation would increase and the role manipulation would decrease this tendency. Analysis of

[5] Questions were also included to assess a number of potential confounds. For example, as was indicated above, we wished to distinguish explicitly the variable of interest in the present research from the anticipation of future interaction (Shapiro, 1975). It is noteworthy in this regard that subject groups proved not to differ from each other in their expectations of future interaction, expressing uniformly low likelihoods that that would occur. Nor did the groups differ regarding other variables assessed.

[6] As noted above, one subject was deleted because he chose the opposite response from the manipulated input value.

responses to this item, however, revealed a significant Sex × Relationship interaction, $F(2, 108) = 3.09$, $p < .05$ (see Table 1). A Duncan multiple range test revealed that when combined across input levels, females perceived the other as a student like themselves to a greater degree in the person condition than in the role condition ($p < .05$). For males, there was no reliable difference among the means.

The fourth item asked subjects to indicate to what degree they saw the other as a competitor. It was anticipated that the personalizing manipulation would tend to decrease perception of the other as a competitor, and that the role manipulation would tend to increase perception of the other as a competitor. Analysis of subjects' responses to this item revealed a highly significant Relationship × Sex interaction, $F(2, 108) = 7.30$, $p < .001$. This interaction (see Table 1) followed the same pattern as the interaction on the dollar-allocation variable. That is, subjects reported varying feelings of competitiveness according to nature of relationship, but the effects of the relationship variable differed between the genders.

As was anticipated, females perceived the other more as a competitor in the role condition than in the person condition. A Duncan multiple range test indicated that this difference was reliable between the person and role conditions when the input levels were combined, and for the high input condition taken separately ($ps < .05$). Male subjects, on the other hand, tended to perceive the other more as a competitor in the *person* condition than in either the control or role conditions. A Duncan multiple range test indicated that the person condition mean differed reliably from the control and the role condition means ($ps < .05$) when input levels were combined and also differed for the high-input condition taken separately.

As might be expected, based on the similarity between the results on this item and dollar-allocation variable, the degree to which subjects reported perceiving the other as a competitor was reliably related to the dollar allocations they made to themselves, overall $r(118) = .27$, $p < .01$.

Correlations. These postexperimental data provide mixed support for the contention that the relationship manipulations did what they were intended to do. Ratings of uniqueness of the other, knowledge about the other, felt competitiveness (among females), and seeing the other as a student like themselves (among females) were consistent with expectations. But there was a clear reversal of the expected relationship in felt competitiveness among males.

This gender difference was also revealed by correlational analyses. Rated knowledge of the other, which had been influenced by the personalizing information consistently across sex (Table 1), proved to be consistently correlated with perceived uniqueness of the other among the entire subject sample, $r(118) = .38$, $p < .001$; among males taken separately, $r(58) = .26$, $p < .03$; and among females taken separately, $r(58) = .47$, $p < .001$. Among females, neither knowledge of the other nor perceived uniqueness was related to feelings of competitiveness. But both these perceptions correlated positively with felt competition among men, $r(58) = .44$, $p < .001$, and $r(58) = .23$, $p < .04$, respectively.

This pattern of correlations suggests that one unanticipated perceptual–cognitive transformation was responsible for the unpredicted behavior of men in this study. Apparently personalizing information, felt knowledge of the other, and perceptions of the other's uniqueness were translated among men into feelings of competitiveness toward the other. Felt competitiveness, then, influenced even male subjects' allocations in a perfectly intelligible fashion.

Discussion

The primary focus of this experiment was upon the effect of the nature of a relationship on resource allocation. The nature of the relationship, as perceived by the allocating member of the dyad, clearly did influence the way in which that member divided the group earnings. The nature of that influence, however, depended on the gender of the subject.

Allocation Among Females

It was expected that role salience would lead to an equity-based allocation, and person salience would lead to a parity-based allocation, both relative to a control condition in which neither was made salient. Females behaved precisely in this fashion. In the high-input condition, female subjects who were encouraged to view their partners as persons allocated themselves almost exactly 50% of the group's earnings (a parity solution). Female subjects encouraged to view their partners in their competitive role allocated the earnings more in line with the relative perceived input of each member (an equity solution). Although prediction was more ambiguous among subjects led to perceive their own inputs as low, dollar allocations to self in those groups proved to follow the same pattern as that found among high-input subjects. In both cases, women were more willing to concede earnings when the other was perceived as a person than when the other was perceived as a functionary.

Allocation Among Males

Males, on the other hand, responded to the relationship manipulation in a very different way. Among males, allocation did not differ between role and control conditions, hovering only slightly above parity in both cases. Allocation among men was reliably influenced only by the personalizing information, and it was an influence that was opposite to what had been expected. In the person-salient condition, high-input males allocated themselves almost exactly 75% of the group's earnings (an equity solution). Although willing to concede some of their "equitable" earnings to the other in control and role conditions, they were completely *un*willing to do so in the person-salient condition. As was true among females, the same pattern of dollar allocations was retained in low-input groups, although the overall level of self-allocation was reduced.

Allocation and Perceptions of the Other

This pattern among males was not anticipated. But the study yielded additional information that allows some insight into the dynamics behind males' surprising behavior. In order to gain some perspective on the issue, let us reexamine the rationale behind the study. As was noted earlier, both Lerner (1977; Lerner et al., 1976) and Deutsch (1975) have theorized that if one person views the other in a personal way, as a unique individual, as being "like oneself," a parity-based division should occur. Women's ratings and allocations were fully consistent with this reasoning. Among males, in contrast, the effects of the personalizing manipulation fit with some of this characterization (enhanced knowledge of the other, perceived uniqueness), but not all of it. For some reason, the personalizing information induced a highly competitive orientation among men. It seems likely that this difference was the basis for the gender difference in allocation patterns.[7]

Why should personalizing lead to feelings of competitiveness among males? One possible explanation rests on the notion that males are generally more attuned to competitive aspects of the performance/allocation situation than are females, and take such competition more or less for granted. Thus, in same-sex dyads at least, men may be *less capable of extricating themselves from the competition role* in inherently competitive situations than are women. This would fit with the common characterization of males in our culture as "task oriented," whereas females are seen as more "social interaction" oriented (cf. Bakan, 1966; Maccoby & Jacklin, 1974; Parsons & Bales, 1955). When the other person was not particularly salient to them, as was the case in both the role-salient and control conditions, the situation may have been relatively comfortable for males, by virtue of its familiarity. That is, among males this sort of "ritualized" role-based competition would be normal and relatively nonthreatening. But providing specific informa-

[7] The possibility should be acknowledged that males' self-reports of competitive feelings occurred as a function of having made the allocation decision as they did, inasmuch as the self-report occurred after the allocation. Although this possibility cannot be discounted entirely, it appears to suggest very little basis for the pattern of allocations themselves.

tion about the other person made him more salient as an individual. Perhaps this enhanced awareness of the other's individuality made him appear more threatening *as a competitor*. In effect, enhanced salience of the other *person* might have been perceived by male subjects as enhanced salience of their *competitors*. This would account for the fact that males most strongly asserted their position of power in this condition.[8] This interpretation also suggests an important limitation on the theorizing of Lerner (1977) and Deutsch (1975). Specifically, personalizing the other may have the consequences that those theorists predicted only when the personalization *replaces* the competitive role orientation, rather than being *added* to that role orientation.

Implications

It is evident that the nature of the relationship between the members of a dyad has an important impact on reward allocation. At least two factors—the degree to which the other is personalized, and the perceived competitiveness of the relationship—appear to mediate this impact. Moreover, the clear and reliable sex difference in mediation of this effect in the present study makes it evident that future research concerning relationships and reward allocation must also take sex of subject into consideration.

Indeed, this gender difference appears to open fertile ground for future research opportunities. For example, if (as we argued above) the unexpected findings among males reflect a stereotypic "masculine" orientation toward competitive situations, one might expect this effect to be influenced by differences in subjects' sex role orientations (e.g., Bem, 1974, 1977). Another important possibility concerns the type of person who is portrayed to subjects. That is, all personalizing information is not alike, and we examined only one type of personalization in this experiment. Perhaps other portrayals might lead males to perceive their partner as deserving egalitarian rather than competitive treatment. Similarly, there may also be portrayals that would induce an especially competitive orientation among females.

These are only two among many possibilities. There can be little doubt, however, that men and women differ in important ways in how they perceive personal relationships and in what cues they use to define those relationships. These differences between the sexes remain an important area of scientific investigation.

---

[8] Inspection of the raw data shows that 5 subjects out of 120 allocated all the money to themselves. All were males in the person-salient condition, 4 in the high-input group, and 1 in the low-input group.

Allocation of Attention and the Type A Coronary-Prone Behavior Pattern

Karen A. Matthews
Department of Psychiatry
University of Pittsburgh

Bradford I. Brunson
Kansas State University

Three studies were conducted to assess the attentional style of individuals with the Type A coronary-prone behavior pattern. Experiment 1, which made use of a dual-task paradigm, revealed that Type A's focus their attention on central tasks; thus, they attend less to peripheral tasks than do Type B's. Experiments 2 and 3, which used a single task performed in the presence of a distracting stimulus, indicated that Type A's actively inhibit or suppress their attention to task-irrelevant peripheral events that might distract them from task performance. These findings validated anecdotal observations that Type A's appear hyperalert (focused in their attention) but neglect task-irrelevant cues. Previous research has demonstrated that Type A's fail to report fatigue as well as a variety of other physical symptoms of illness during task performance. To the extent that symptoms are analogous to peripheral events that distract from task performance, the data suggest that Type A's suppress their attention to symptoms. Implications of the attentional style of Type A's for the pathogenesis of coronary artery and heart disease are discussed.

A behavior pattern called *Type A* has become widely known for its negative effects on cardiovascular health. Both retrospective and prospective studies have demonstrated that Pattern A is associated with at least twice the occurrence of heart disease as an opposing Pattern B, which is defined as the absence of Pattern A (Friedman & Rosenman, 1974; Jenkins, Rosenman, & Zyzanski, 1974). This relationship remains when statistical controls are introduced to partial out the effects of traditional risk factors for coronary heart disease (CHD), such as serum cholesterol level and systolic blood pressure. Moreover, Pattern A is also associated with the degree of atherosclerosis in the coronary arteries (Blumenthal, Williams, Kong, Schanberg, & Thompson, 1978; Zyzanski, Jenkins, Ryan, Flessas, & Everist, 1976).

Behavioral Characteristics of the Type A

The Type A behavior pattern is defined as "an action–emotion complex that can be observed in any person who is aggressively involved in a chronic, incessant struggle to achieve more and more in less and less time, and if required to do so, against the opposing efforts of other things or persons" (Friedman & Rosenman, 1974, p. 67). Systematic investigations by Glass and his colleagues have verified the existence of a number of behavioral manifestations of this behavior pattern (cf. Glass, 1977). For example, Type A's signal the passage of 1 minute sooner than Type B's do, apparently sensing time passing rapidly (Burnam, Pennebaker, & Glass, 1975). When frustrated, Type A's become aggressive and hostile (Carver & Glass, 1978; Glass, Snyder, & Hollis, 1974). Type A's work at near their maximal rate even when there is no explicit time deadline (Burnam et al., 1975; Carver, Coleman, & Glass, 1976).

The authors thank Chuck Carver, Kent Houston, Michael Scheier, and Richard Jennings for their helpful comments on an earlier draft of this manuscript, and David Hufford and Kathy Menna, who performed ably as experimenters.

Simultaneously they report less fatigue and other physical symptoms than B's do (Carver et al., 1976; Weidner & Matthews, 1978).

One behavioral attribute of Type A's that has not been systematically investigated is their policy for allocating attention to environmental events. This is indeed surprising, considering that policies for allocation of attention play a critical role in such diverse behaviors as experiences of affect and bodily states (Gibbons, Carver, Scheier, & Hormuth, 1979; Scheier & Carver, 1977), human judgments (Taylor & Fiske, 1978), and attainment of performance goals (Carver & Scheier, Note 1). We suggested elsewhere that Type A's and Type B's might differ in how they allocate their attention to the environment and that this difference might explain why Type A's report less severe physical symptoms than Type B's do while performing a stressful task (Weidner & Matthews, 1978). Specifically, we reasoned that because of Type A persons' chronic efforts to achieve, they devote their full attention to tasks at hand. Consequently, they do not notice peripheral events that are not immediately relevant to task performance, such as physical symptoms or subtle cues of another's distress. In other words, Type A's focus their attention on environmental stimuli that will aid them in their efforts to excel. This notion is consistent with descriptions of Type A individuals as being extraordinarily alert but inattentive to extraneous cues (Bortner & Rosenman, 1967; Friedman & Rosenman, 1959; Rosenman & Friedman, 1961) and with the argument advanced by Glass (1977) that only *highly salient* tasks elicit controlling behavior from Type A's.

Do A's differ from B's in the policies by which they allocate attention to their environment? The purpose of the present research was to assess this possibility. Our major hypothesis was that Type A's focus their attention on central aspects of their environment; consequently they attend less to peripheral aspects than Type B's do. To test this notion, the first experiment used a dual-task paradigm (e.g., Bahrick, Fitts, & Rankin, 1952; Hockey, 1970; Kahneman, 1973) in which one task was defined as central or primary and one task was defined as peripheral or secondary through physical arrangements of the tasks and experimenter instructions. Assumptions of this paradigm are that humans have a limited capacity of attention and that performance on the two tasks varies with the amount of attention allocated to them, provided that the capacity of the individual is fully used. Focusing of attention is said to occur when performance on the secondary task is poor and performance on the central task is the same or good, compared to a referent.

In Experiment 1, Type A and B undergraduates worked for 6½ minutes on two tasks simultaneously. The primary task was the Stroop Color Naming Task (Stroop, 1935), and the secondary task was to depress a telegraph key upon the onset of a light, located at the right periphery of the field of vision. We expected that Type A's would allocate less attention to the secondary task than Type B's would; they would allocate as much and perhaps more attention to the primary task than Type B's would. Consequently, Type A's should perform poorer on the reaction time task and the same or better on the Stroop Color Naming Task than B's should.

Experiment 1

Method

Subjects. Subjects were 23 undergraduates enrolled in introductory psychology courses at Kansas State University who gained course credit by participating in research. Subjects were classified as Type A or B on the basis of their scores on the Jenkins Activity Survey (JAS) (Jenkins, Zyzanski, & Rosenman, 1971) revised for students by Glass (1977). In large samples of undergraduates the median of the JAS falls between 7 and 8 (Glass, 1977). Type A's were those who scored above the median of this sample of subjects (8.0 and above), whereas Type B's were those who scored below the median (7.0 and below). Two female Type A's were deleted because of equipment failure, one female Type B for failure to follow instructions. The final sample contained 10 Type A's and 10 Type B's; half of each group was male, half female. None were color blind, and all were native English speakers. Nonnative English speakers did not participate because they answer the JAS questions from a different cultural referent (see Cohen, 1978, for a discussion of this point).

Materials and apparatus. Directly in front of the subjects on a table were the materials for the primary task, the Stroop Color Naming Task

(Stroop, 1935) modified by Hartley and Adams (1974). The materials were a stack of sheets that contained 30 lines of six color names; each color name was printed in a color of ink other than its own color name. Each line contained one stimulus color name on the left and five possible choices of color names on the right. Subjects were to circle with a pen in their dominant hand the color name of the stimulus word's ink among the five choices.

The apparatus for the secondary task, a simple reaction time task, was located in the subject's right field of vision.[1] At approximately two o'clock in the visual field was a 12 inch × 12 inch (30.5 × 30.5 cm) black vertical panel on which was mounted a 1-inch (2.54 cm) square red light. At the base of the panel was a telegraph key secured to the horizontal platform adjoining the panel. During the 6½ minutes of the experiment, the light was activated 12 times; the intertrial interval averaged 20 sec, but varied from 10 to 30 sec. The duration of the light was 10 sec unless the subject terminated the light by depressing the telegraph key. The time to depress the key was measured in milliseconds by a Lafayette 54517 clock in conjunction with a digital printer.

Procedure. Subjects were tested individually. A female undergraduate experimenter greeted the subjects and explained that they would participate in two studies. After giving a brief overview of the two studies, she obtained their consent to participate in the research. In the first study, subjects were asked to complete the JAS because the experimenter wished to collect normative data on the life styles of college students. Following completion of the JAS, subjects filled out a second questionnaire while the experimenter scored the JAS. Then subjects were escorted to another testing room for the second study and were greeted by a male experimenter, a graduate student, who remained blind to their Type A–B categorization.

The second experimenter explained that they would be involved in an experiment designed "to test the effects of extraneous stimuli on task performance." He instructed the subjects on how to do the Stroop Color Naming Task and allowed them to practice until they solved several correctly in a row. Then he informed them that they would have about 6 minutes for this task and that they should work as fast and accurately as they could. A time deadline was imposed because Type A's and B's tend to perform at a similar maximal rate when there is such a time deadline (Burnam et al., 1975). Finally, almost as an afterthought, he said, "In addition to working on this Stroop task, I want you to press this telegraph key every time you notice this light come on." After several practice trials turning off the light, the instructions for the Stroop task were reviewed briefly, subjects began working, and the experimenter left the room. After 6 minutes had passed, the experimenter turned off the reaction time apparatus and returned to the testing room. (As a result, subjects worked on the Stroop task for approximately 6½ minutes.) Then he administered a postexperimental questionnaire and fully debriefed them.

Table 1
Performance by Type A's and Type B's on Secondary and Primary Tasks

Dependent measure	Type A	Type B
Secondary task		
M reaction time to each light[a]	4.14	1.97
Number of noticed lights[b]	10.3	11.8
M reaction time to each noticed light only[a]	3.18	1.83
Primary task		
Number of Stroop problems completed correctly[b]	165.0	106.7

[a] The *lower* the number, the better the performance on this measure.
[b] The *higher* the number, the better the performance on this measure.

Results and Discussion

Performance on the secondary and primary tasks and items on the postexperimental questionnaire were analyzed by 2 (Type A–B) × 2 (Sex of Subject) analyses of variance. Because there were no significant effects for sex of subject in any of the analyses, only analyses by type are reported. Table 1 presents the mean Type A and B scores for the following dependent measures: (a) mean reaction time to each of the 12 lights, (b) number of lights noticed (as indicated by depression of the telegraph key prior to automatic turning off of the light), (c) mean reaction time to each of the noticed lights (all measures from the secondary task), and (d) the number of problems completed on the Stroop Color Naming Task (the primary task).

Secondary task performance: Reaction time to lights. We expected that Type A's would attend less to the secondary task than would Type B's and consequently would react more slowly to the onset of the stimulus

[1] For the one left-hander in the study, the apparatus was switched to the subject's left field of vision, and he was required to press the reaction time key and circle the correct response on the Stroop task with his left hand.

light than Type B's would. As row 1 of Table 1 reveals, the mean reaction time to each of the 12 lights was significantly greater for Type A's than for Type B's, $F(1, 16) = 31.98$, $p < .001$. In addition, Type A's failed to notice as many lights as did Type B's (see Table 1, row 2), $F(1, 16) = 12.16$, $p < .003$. Because it was possible that the mean reaction time to the lights was greater for A's than for B's simply because A's did not notice as many lights as B's did, we also examined the mean reaction time to each light that had been noticed. As row 3 of Table 1 shows, Type A's were significantly slower than B's to react to these lights, $F(1, 16) = 17.88$, $p < .001$.[2]

Primary task performance: Stroop Color Naming Task. If Type A's focus their attention on the primary task, they should perform the same or better on the Stroop Color Naming Task than should B's. As row 4 of Table 1 reveals, Type A's did correctly complete significantly more Stroop problems than Type B's did, $F(1, 16) = 27.92$, $p < .001$.[3]

Postexperimental questionnaire. In response to items on a postexperimental questionnaire, Type A's believed that they performed better on the Stroop task than Type B's believed they performed, $F(1, 16) = 5.65$, $p < .03$. There were no other significant effects for sex or type on ratings of difficulty of the Stroop task, quality of performance on the reaction time task, disruptive effect of responding to the light on the Stroop task performance, or the importance of the research.

In summary, the results of Experiment 1 indicate that, relative to Type B's, A's perform more poorly on the secondary task and better on the primary task. It is worthwhile noting that the precise rewards for excelling on the primary and secondary task were left ambiguous in this study. We chose to do this to maximize the possibility that individual differences in allocation of attention would emerge. In fact, we suspect that should precise rewards be established, both A's and B's would be capable of allocating their attention to receive maximum reward. In other words, both types might behave similarly in explicit situations, for example, when performance on secondary tasks is highly rewarded. Nonetheless, the results support the notion that A's focus their attention on central environmental events. Thus, they allocate less attention to peripheral tasks than do B's in relatively unstructured settings.

Because A's attend less to peripheral tasks than B's do, it is reasonable to extrapolate that they also attend less to task-irrelevant peripheral events. Experiment 1 did not, however, address the issue of how active this inattentiveness of A's to peripheral events might be. That is, the presence or absence of a task-irrelevant peripheral event may simply be inconsequential for A's, who are attending to task performance. Alternatively, however, it may be that Type A's actively inhibit their attention to such peripheral events.

Experiment 2 was conducted to compare these two possibilities. In Experiment 2 we began by assuming that task-irrelevant sounds are peripheral events that can distract from task performance if attention is directed to them. Previous research has shown that the presence of extraneous noise improves Stroop color naming performance (Hartley & Adams, 1974). Apparently this occurs because subjects presented with a noise actively inhibit their attention to the noise; in doing so, they also inhibit their attention to other task-irrelevant cues—including the name of the color of the stimulus word (Houston, 1968, 1969; Houston & Jones, 1967). Thus, performance is better as subjects are less distracted by even the distractor that is inherent in the task. This fact allows us to ascertain whether Type A's actively inhibit their attention to the extraneous sounds or whether this peripheral event is simply inconsequential in the following way. If Type A's attend less to task-irrelevant peripheral events than

---

[2] On this measure only, there was a marginally significant interaction term, Sex × Type A–B, $F(1, 16) = 4.21$, $p = .06$. Although both male and female Type A's were slower than male and female Type B's, the difference between the types was larger for males than for females.

[3] Analyses of the number of *attempted* Stroop problems for Experiment 1 also revealed the same pattern of results: Type A–B, $F(1, 16) = 27.85$, $p < .001$. There were no significant effects in percentage of errors.

B's do simply because they are attending to the central task, then the Stroop performance of A's should not be affected by the presence or absence of a distractor. On the other hand, if Type A's actively inhibit their attention to distractors, the performance of A's should be facilitated by the presence of a distractor. To compare these possibilities, Type A and B undergraduates performed the Stroop Color Naming Task either in the presence or in the absence of a tape of distracting sounds. Each subject was given an explicit time deadline of 5 minutes to insure that both A's and B's worked at the same high rate (cf. Burnam et al., 1975).

Experiment 2

Method

Subjects. Subjects were 22 male and 21 female undergraduates enrolled in introductory psychology courses at Kansas State University who obtained course credit for their participation. Subjects were classified as Type A (9.0 and above on JAS) or Type B (6.0 and below) prior to experimental procedures.[4] One Type B woman was deleted from the analyses because of her failure to follow instructions. In the final sample, there were 11 Type A's and 10 Type B's in the distractor group and 10 Type A's and 11 Type B's in the no distractor group. None were color blind; all were native English speakers.

Procedure. Subjects were tested individually. A female undergraduate greeted the subjects, and as in Experiment 1, she explained that they would participate in two studies. After giving a brief overview of the studies, she obtained their consent to participate in the research. Then, during the first study, the JAS was administered. After subjects completed the JAS, they completed a second personality quiz while the experimenter scored the JAS and assigned subjects to either the distractor or the no distractor group. She then escorted subjects to an adjoining testing room where she introduced them to a male experimenter and informed the experimenter of the subjects' stimulus group assignment but did not inform him of the subjects' Type A–B score.

The second experimenter explained to subjects in the distractor group that the study concerned the effects of noise on task performance or to subjects in the no distractor group that the study concerned the effects of visual interference on task performance. Subjects were then given instructions identical to those in Experiment 1 as to how to perform the Stroop Color Naming Task and were told that they had a time deadline of 5 minutes and to work as accurately and quickly as possible. In addition, subjects in the distractor group were told that they would be exposed to a tape of sounds through headphones while they were working on the Stroop task. The tape contained continuous electronic music interspersed with such common sounds as a sports broadcast, brief verbal remarks, and a ticking clock. The average intensity of the sounds was 78 dB(A), 3000 Hz measured at the headphones with the aid of a coupler device.[5] The range was 72 to 85 dB(A). The no distractor group were also asked to wear headphones, but of course the tape was not played for them. Subjects then worked on the Stroop task until the experimenter stopped them after 5 minutes. Subjects completed a questionnaire concerning their perceptions of the experiment; questions concerning perceptions of the sounds were not administered to no distractor subjects. All subjects were questioned regarding their suspicions of experimental procedures and were then fully debriefed.

Results and Discussion

Except for ratings of the sounds, the data were analyzed by 2 (Type A–B) × 2 (No Distractor – Distractor Groups) × 2 (Sex of Subject) analyses of variance.

Performance on the Stroop Color Naming Task. We expected that if relative to Type B's, Type A's attend less to peripheral events simply because they attend more to central events, they should not perform better in the presence of a distractor. However, if Type A's actively inhibit their attention to the distractor, the presence of the distractor should facilitate their performance. In either case, there should be no differences in the types' performance in the no distractor condition because the types work at a similar rate with a time deadline (Burnam et al., 1975), and in general, performance should improve in the presence of sounds. As row 1 of Table 2 indicates, A's did perform better with a distractor than without. There were no differences in the performance of A's and B's without a distractor. The analysis of variance confirmed this pattern of results with a statistically significant interaction term, Type A–B × Distractor – No Distractor Group, $F(1, 34) =$

[4] There were 10 additional subjects who scored at 7.0 or 8.0 on the JAS who were a priori excluded from the study.

[5] This tape was designed to be similar to the Houston (e.g., 1968) tape of sounds in dB(A) level as well as in type of random sounds. The tape was distracting but not aversive.

Table 2
Number of Stroop Problems Completed Correctly by Type A's and Type B's

	Distractor				No distractor			
	Type A		Type B		Type A		Type B	
Experiment	No.	*n*	No.	*n*	No.	*n*	No.	*n*
2	113.0	11	81.7	10	93.5	10	97.5	11
3	125.1	9	104.2	10	101.5	8	95.2	9

5.90, $p < .02$, and a significant main effect for Type A–B, $F(1, 34) = 4.16$, $p < .05$.[6] Internal contrasts revealed that Type A's performed significantly better in the presence of a distractor than without, $t(19) = 2.14$, $p < .05$, and outperformed B's in the distractor condition, $t(19) = 3.44$, $p < .01$. Unexpectedly, however, Type B performance tended to worsen with distraction, $t(19) = 1.73$, $p < .10$. There were no other significant effects, including those for sex of subject.

Postexperimental questionnaire. Type A's rated the tape of sounds as more unpleasant on a 7-point scale than Type B's did (Ms = 3.3 vs. $M = 4.7$, respectively), $F(1, 17) = 4.80$, $p < .05$. Women rated the tapes as significantly louder and more stressful than men did, Fs$(1, 17) > 4.63$, ps $< .05$. There was a significant interaction term for ratings of task difficulty, Distractor – No Distractor Group × Sex of Subject, $F(1, 34) = 4.05$, $p = .05$. Although female subjects rated task difficulty similarly in the two groups, men in the distractor group thought the Stroop task was less difficult than those in the no distractor group did. There were no other significant differences across types, distractor conditions, or sex of subject for ratings of quality of performance, importance of research, and distractibility of the distractor.

In summary, the results of Experiment 2 are consistent with the notion that Type A's inhibit their attention to task-irrelevant peripheral events. Unexpectedly, Type B performance tended to deteriorate with distraction. Thus, we did not replicate previous research that indicates distracting sounds lead to improved performance overall on the Stroop test. Therefore, in order to examine the reliability of the Type B responses to distraction, we decided to replicate Experiment 2.

Experiment 3

Method

Subjects. Subjects were 18 male and 19 female undergraduates enrolled in introductory psychology courses at Kansas State University who obtained course credit for their participation. Subjects were classified as Type A (8.0 and above) or Type B (7.0 and below) prior to experimental procedures and assigned to cells so that an approximately equal number of Type A men and women and Type B men and women were in each group. One Type A man was deleted because of his failure to follow instructions. In the final sample, there were 9 Type A's and 10 Type B's in the distractor group and 8 Type A's and 9 Type B's in the no distractor group. None were color blind; all were native English speakers.

Procedure. The procedure was identical to that used in Experiment 2 with one exception. Subjects were administered the JAS during one test session. At that time, the female experimenter scheduled them for a second session one or two weeks later during which they were administered the Stroop Color Naming Task. As before, the experimenter for the second session was blind to the subjects' Type A–B score.

Results and Discussion

Performance on the Stroop Color Naming Task. As in Experiment 2, Type A's performed better with a distractor than without (Table 2, row 2). There were no differences in the performance of A's and B's without a distractor. In contrast to the results of Ex-

[6] Analyses of the number of *attempted* Stroop problems for Experiment 2 also revealed the same pattern of results: Type A–B × Distractor – No Distractor Group, $F(1, 34) = 5.60$, $p < .03$. There were no significant effects in percentage of errors.

periment 2, B's did not deteriorate in their performance in the presence of a distractor. The analyses of variance confirmed this pattern of results with a significant main effect for distractor – no distractor group, $F(1, 28) = 4.17$, $p = .05$, and no other significant results. Internal contrasts revealed that the main effect was largely due to Type A individuals' behavior. Type A's improved in their performance in the presence of a distractor, $t(15) = 2.09$, $p < .06$, whereas B's did not, $t < 1$. Type A's tended to perform better than B's did in the distractor group, $t(17) = 1.95$, $p = .07$. There were no other significant effects, including those due to sex.[7]

Postexperimental questionnaire. Women rated the tape of sounds as more distracting on a 7-point scale than did men, $F(1, 15) = 7.03$, $p < .02$. There were no other differences across types, distractor conditions, or sex of subject for ratings of task difficulty, quality of performance, and loudness, stressfulness, and pleasantness of the distractor.

The results of Experiment 3 replicate previous research that distracting sounds aid performance on the Stroop Color Naming Task. Taken together, the results of Experiments 2 and 3 reveal that this effect is primarily due to the Type A's. Apparently Type A's are able to inhibit their attention to the sounds. By doing so, they can actively ignore task-irrelevant cues and their performance improves.

General Discussion

The results of the three experiments are consistent with the hypothesized differences in the types' policies for allocating attention to the environment. It might be argued, however, that the results were due to an unfortunate selection of tasks such that Type A's simply are better on the Stroop Color Naming Task and poorer on simple reaction time tasks than Type B's are. This explanation is rendered much less plausible, though, by the similar Stroop performances of A's and B's without distraction in Experiments 2 and 3, and the lack of consistent differences in the simple reaction times of A's and B's in other studies (Abrahams & Birren, 1973; Krantz & Matheson, Note 2; Spieth, 1965). Therefore, performance differences of A's and B's on the tasks probably reflect true differences in allocation of Type A and Type B individuals' attention to the environment in these laboratory investigations.

In summary, then, the present findings provide the first systematic documentation of Type As' policy for allocating attention to the environment. They focus their attention on central environmental information; consequently, they attend less to peripheral aspects than Type B's do. Moreover, Type A's can actively inhibit their attention to peripheral events that might distract them from performing well on a task. These findings verify anecdotal observations that Type A's appear hyperalert but are less able than B's to report task-irrelevant (peripheral) cues (e.g., Bortner & Rosenman, 1967).

Arousal and Type A Individuals' Allocation of Attention

It is documented that arousal leads to a focusing of attention and to attention to the most task-relevant or salient cues (Easterbrook, 1959). Also, accumulating evidence shows that Type A's have greater increases in indices of sympathetic nervous system arousal than Type B's do while performing challenging tasks, although no differences between the types exist in resting levels (e.g., Dembroski, MacDougall, & Shields, 1977; Friedman, Byers, Diamant, & Rosenman, 1975; Manuck, Craft, & Gold, 1978). It could be argued that if A's in our studies were more aroused than B's, they attended more to the salient aspects of the Stroop task—in this case, to the color of the stimulus word's print—and ignored relatively irrelevant aspects, like the name of the Stroop stimulus word, the secondary task in Experiment 1, or the tape of sounds in Experiments 2 and 3. Thus, it is feasible that differences in arousal underlie the differences in the types' policies of attention allocation.

---

[7] Analyses of the number of *attempted* Stroop problems for Experiment 3 also revealed the same pattern of results: distractor – no distractor group, $F(1, 28) = 4.48$, $p < .05$. For error rates there was a significant interaction term, Distractor – No Distractor Group × Sex of Subject, $F(1, 28) = 5.11$, $p < .05$. Males had a larger percentage of errors in the no distractor than in the distractor group, whereas females showed the reverse pattern.

While this possibility is attractive in some respects and may be true for a variety of situations, it has a number of negative features as an explanation of the findings from Experiments 2 and 3. First, it is inconsistent with physiological evidence of cardiac deceleration during Stroop performance, which is associated with deliberate pacing used by subjects to reduce errors and confusion (see Kahneman, 1973). Second, it cannot explain why Type A's (presumably aroused) do not outperform Type B's in the no distractor group in the latter two experiments unless one assumes that the Stroop task alone is insufficiently challenging to create arousal. For the arousal hypothesis to fit the existing data, we must assume that Type A's were aroused while executing the Stroop task *only* in the presence of distracting sounds. But this assumption is inconsistent with the absence of arousal (measured by pulse rate) in subjects working on the Stroop task while listening to 78 dB(A) sounds (Houston & Jones, 1967). Presumably some of those subjects were Type A's. Finally, discernible arousal generated in ways other than noise (e.g., threat of shock) has a detrimental effect on performance of the digit symbol test, a subtest of the Wechsler Adult Intelligence Test (Carlson & Lazarus, 1953; Goldfarb, 1961), in contrast to distracting sounds, which have a facilitating effect (Houston, 1968). Type A's but not Type B's show significant improvement in their performance of the digit symbol test in the presence of distracting sounds (Matthews, Note 3), just as was true of the present Stroop performance. For these reasons, we do not favor an arousal interpretation of Type As' allocation of attention in Experiments 2 and 3, although we do expect that Type A individuals' sympathetic nervous system arousal affects their attentional style in other situations. In future research, therefore, we plan to examine the physiological correlates of Type As' attentional style in a variety of settings.

Implications for Previous Research

The differences in the types' allocation of attention to the environment provide a plausible interpretation of Type As' reactions to the salience of uncontrollable events (Glass, 1977). Type A's respond to highly salient losses of environmental control by making greater initial efforts than B's do to reassert control, followed by more extreme giving up relative to B's. When the uncontrollable event is moderately salient, Type A's actually make less effort than Type B's do to reassert control and do not give up, whereas Type B's do. Glass (1977) suggests that because of Type A persons' need to avoid losses of environmental control, they distort uncontrollability cues if they are not highly salient, or at least they do not effectively encode them. However, contrary to this suggestion is the absence of differences between A's and B's in perceptions of uncontrollability (Glass, 1977). On the other hand, the present data suggest that Type A's attend to the most salient aspects of their environment and inhibit their attention to any peripheral cue that might deter them from an excellent performance. This attentional interpretation of the salience findings can explain Type As' lack of responsiveness to uncontrollable events of low salience. It does not explain why Type B's do not give up following highly salient uncontrollable events, given that they do give up following moderately salient ones.

As stated earlier, our initial speculations about the attentional styles of Type A's were derived from our attempt to explain their failure to report symptoms during task performance. Indeed, the results of the present research are consistent with an attentional explanation of this phenomenon. That is, to the extent that symptoms are analogous to distractors from task performance, the data suggest that Type A's can inhibit their attention to symptoms. Tesser (e.g., Sadler & Tesser, 1973) has shown that the greater the amount of attention to an event or experience, the more extreme the evaluation of it. During task performance, then, Type A's may rate their symptoms as less extreme than B's do because they attend to them less than B's do.

We have stated elsewhere (Weidner & Matthews, 1978) that the term "suppression" was inappropriate to describe Type As' failure to report symptoms because it implied that we knew the mechanism underlying this phenomenon. At that time, we had no evidence why Type A's might fail to report symptoms. The present data, however, suggest that the

term *suppression* is appropriate to describe Type As' failure to report symptoms in the limited sense that Type A's *suppress their attention* to symptoms. It is important to emphasize that existing data do not suggest that A's have less sensory input of symptoms than do B's. That is, physiological indices of effort and sympathetic arousal are often greater or the same for A's relative to B's during task performance (Carver et al., 1976; Weidner & Matthews, 1978). It is also important to note that Type As' suppression of attention to symptoms is not the same as denying or distorting the truth in order to avoid admitting the disruptive effects of symptoms on task performance. Type A's report as much disruption of task performance from the distractor in Experiments 2 and 3 and from symptoms (Weidner & Matthews, 1978) as Type B's do. Rather, suppression appears to be a useful strategy for maintaining and even accelerating the efforts of Type A's, certainly a strategy that Type A's might seek out given their needs to achieve (see Carver et al., 1976).

Relevance to Heart Disease

We have observed elsewhere that failure of Type A's to report symptoms may contribute to Pattern A risk of coronary artery and heart disease in two ways (Weidner & Matthews, 1978). First, Type A's may delay seeking medical attention when experiencing early heart attack symptoms (Carver et al., 1976). With increasing delays, prodromal symptoms are more likely to result in a full-fledged heart attack and an ongoing infarction becomes more severe. In fact, delay is in itself a risk factor for heart disease (Insull, 1973). Second, Type A individuals' failure to report symptoms does not allow them to use symptoms elicited by stress as cues to alter their behavior to less stressful forms. To the degree that the attentional style of Type A's can account for their failure to report symptoms, this style may contribute to Pattern As' risk for heart disease. Furthermore, the attentional style of Type A's may also play a third, more critical role in the etiology of heart disease. Individuals who are described as hyperalert and who exhibit a high level of ability to focus their attention also show correlated increase in sympathetic nervous system activation (Williams, Note 4). If such activation were to occur repeatedly, it would subject the cardiovascular system to substantial physical loads on a daily basis, which might result in eventual heart disease (Williams, 1975). Indeed Williams (1975) has speculated that the perceptual and attentional aspects of Pattern A might provide the intervening link between Pattern A and coronary disease pathogenesis. The present research offers evidence that the above "coronary-prone" attentional style is consistent with Type A persons' style of attending to their environment. Thus, the attentional style of Type A's may serve them well in the sense of allowing them to focus their attention on work and to ignore annoying distractions, but it may also place them in triple jeopardy for coronary artery and heart disease in their later years.

The Power Motive as an Influence on Use of Power

Eugene M. Fodor
School of Management

Dana L. Farrow
Division of Management
Florida International University

An industrial simulation experiment was conducted with students earning a master's degree in business administration to determine the influence of the power motive on their use of power. Need for power was assessed by means of the Thematic Apperception Test measure devised by Winter. Students scoring among the top and bottom third of those taking the test then proceeded to act as "supervisor" in the industrial simulation by directing the labors of a work crew in the next room. One member of the crew, Man C, behaved as an ingratiator. Supervisors high and low on *n* Power evaluated Man C about the same when he was neutral and noningratiating in his manner, but when Man C was an ingratiator, supervisors high on the power motive evaluated his performance more favorably than did low-scoring supervisors. High *n* Power supervisors also perceived themselves as exerting greater influence on the work group. These findings are seen as extending the heuristic value of the *n* Power construct by demonstrating its relationships to use of power in an industrylike situation.

Organizational supervisors typically have at their disposal a variety of powers over subordinates. Depending on the nature of the organization, these powers may include the power to grant raises, recommend promotion, recommend transfer to a more fulfilling job assignment, and even discharge subordinates for inadequate performance. It is surely axiomatic that supervisory use of power can substantially influence employee morale and need fulfillment. One would expect that a supervisor would promote need fulfillment among subordinates if he allocated benefits in a manner that was closely contingent on their quality of performance (Porter & Lawler, 1968). Conversely, need fulfillment would probably diminish to the extent that the supervisor distributed rewards on the basis of arbitrary criteria that were extraneous to recognized organizational objectives.

The purpose of the present investigation was to examine the relation between the power motive and use of power by persons acting as supervisor in an industrial simulation experiment. Need for power was assessed by means of the Thematic Apperception Test (TAT) measure devised by David Winter (1973). The experimental design represented a variation of the paradigm developed in studies reported by Goodstadt and Kipnis (1970) and Kipnis and Vanderveer (1971).

Studies that examined only situational influences on use of power have yielded inconsistent findings. Kipnis and Vanderveer (1971) found that persons acting as supervisor in an industrial simulation gave more pay increases and higher performance evaluations to an ingratiator than to a worker of similar performance who was not an ingratiator. A later experiment (Fodor, 1974) was unable to replicate these findings. Some studies have suggested that the presence of a problem worker increases the likelihood that a supervisor will regard with favor a compliant member of the work crew (Fodor, 1974; Goodstadt & Kipnis, 1970; Kipnis & Vanderveer, 1971). Another investigation obtained opposite findings (Fodor, 1976).

Grateful acknowledgment is expressed to Robert Conforti, Clifton King, and Robert Zogg, who served as experimenters.

An influence unexplored in these studies was the variable of individual differences in motivation or in some dimension of personality. A likely candidate for consideration emerged with Winter's publication of *The Power Motive* (1973). By need for power, Winter means a need to influence, persuade, or control others and to gain recognition or acclaim through these forms of behavior. He developed a measure of need for power that is based on the TAT much in the same manner as McClelland's concept of achievement motivation (McClelland, 1958; McClelland & Winter, 1969). The Winter scoring system builds upon TAT criteria of need for power previously put forth by Veroff (1957) and Uleman (1966) and adds numerous refinements of its own. One method Winter used for selecting scoring categories was to administer the TAT both before and after exposure to an event that was replete with power imagery (John Kennedy's inaugural address) and then to note what categories of TAT imagery increased in frequency of usage. Winter completed a number of investigations in an attempt to establish the validity of his scoring system. Students who were or had been officers in student organizations scored higher on need for power than those who were not. Resident advisers obtained high scores. These students, it should be recognized, occupy positions of considerable influence and respect in the university community. They serve as academic and personal counselors for students, give advice, and act as the liaison between students and the administration. Athletes who engaged in competitive sports likewise scored high.

A major problem associated with experimentally derived TAT measures of motives has been low test–retest reliability (Atkinson, 1958). Winter and Stewart (1977) have presented evidence, however, that low temporal stability may derive from an implicit demand for novel stories during the second test administration. The problem substantially diminished when they instructed subjects at the retest either (a) not to worry about whether their stories were similar or different or (b) to try to write the same stories. Subjects instructed to write different stories produced reliability only at chance levels.

Winter's conceptualization implies that in their quest for recognition and acclaim, persons high in power motivation would probably respond favorably to persons supplying them with unswerving support and loyalty in the form of ingratiation. The principal hypothesis of the present experiment was that persons scoring high on need for power would dispense greater benefits on an ingratiating subordinate than would individuals low in power motivation. Persons scoring high were also expected to differentiate more broadly between two compliant but noningratiating workers of comparable performance in the pay increases and performance evaluations that they awarded. The assumption guiding this prediction was that those who are strongly dominated by power concerns take satisfaction in the exercise of power for its own sake and are apt to allocate benefits to subordinates in an arbitrary and whimsical fashion. The two compliant but noningratiating workers were equal in performance, appearing to deserve equal pay increases and performance appraisals. The expectation, however, was that supervisors high on the power motive would allow personal preference based on a subordinate's voice quality or some casual remark to take precedence over more objective performance criteria, causing them to make sharp distinctions between these two seemingly equal subordinates. A further prediction was made that high scoring persons would "read" members of the work crew as having been highly susceptible to their supervisory influence. They would report that they had exerted greater influence on the work group than would low-scoring supervisors.

Method

Subjects

Male students enrolled in the master's in business administration (MBA) program at Clarkson College served as experimental subjects. MBA students are preparing for careers as business managers and as a consequence of exposure to organizational behavior courses, they have begun to reflect on what style of leadership they should employ in their ultimate career role. The requirement that they act as supervisor in an industrial simulation it was therefore presumed, should for them have greater "experimental realism" (Aronson & Carlsmith, 1969) than for the typical undergraduate

Students were contacted by phone and were offered $2.50 to complete the TAT. They were told that they would be paid a like sum should they later be asked to participate in the industrial simulation. One hundred and twenty-two MBA students completed the TAT, and those scoring in the top and bottom third of the group on need for power were invited to return for the industrial simulation. This process was continued until a total of 80 students had successfully performed in the experiment. Subjects were assigned randomly to the two conditions.

The TAT Measure of Need for Power

There is no standard set of pictures for use in measuring power motivation, so eight pictures were selected that connoted some degree of power imagery. One was a scene from a football game, another was the photograph of a young man speaking to a crowd through a bullhorn, and a third depicted a well-dressed man passing a less well-dressed younger man standing against a wooden fence. Three of the pictures were taken from the set compiled by McClelland, Davis, Kalin, and Wanner (1972).

The Winter scoring manual sets forth a procedure that enables the researcher to attain high interrater reliability in the scoring of TAT stories for power imagery. The researcher first attempts to score four sets of 30 stories, checking the accuracy of his or her scoring against the standard after completion of each set. Three final sets are then scored for the purpose of obtaining an estimate of scoring proficiency. Winter describes two indices of interrater reliability. One is "category agreement," which measures level of agreement with the standard for presence or absence of power imagery, and the second is a rho coefficient that assesses correlation of ranks between one's own scoring and the standard. Winter recommends that the investigator regard a coefficient of .85 on both reliability measures as a prerequisite to research application of the Winter scoring system. The first author succeeded in meeting these criteria by obtaining a category agreement of .94 and a rho coefficient of .88.

To obtain an estimate of the stability of Winter's measure, two different sets of four pictures were presented to a class of 20 undergraduate students on each of two occasions separated by a span of 2 weeks. Scores for each story range from 0 to 11, and a total score can be computed by simply averaging scores across stories; so an overall score can be obtained on the basis of only four of the eight pictures. The Spearman–Brown formula yielded a stability coefficient of .46 for this split-half administration. Seventy-five male MBA students took the complete test at one sitting, and a division of scores placed them into a top, medium, and bottom third. Viewed against these points of division, only 1 of the 20 undergraduates changed position by more than an adjacent category from one administration to the next. Ten students remained within their third of the distribution across administrations. The test would appear to have research value if interest were confined to the behavior of persons scoring at the top and bottom third of the distribution, that is, those distinctly high or low on need for power.

Procedure

The experimenter informed subjects upon their arrival at the laboratory that the purpose of the industrial simulation was to study their managerial ability. They would, he told them, assume the role of supervisor and direct the work activities of three college men in the next room (who, unknown to the supervisor, would actually be nonexistent). The supervisor was further given to believe that individual workers had been assigned the task of assembling Tinker Toy models from pictured diagrams. These workers were to assemble as many models per trial as they were able, and which model they were to put together would change on each of five successive 5-minute trials. Each trial was followed by a 5-minute rest period. Successive trials featured models that were progressively more difficult to construct: a pair of eyeglasses, a tire swing, a teeter-totter, a hand winch for cranking up rope, and a windmill. The supervisor was expected to use every means at his disposal to foster high productivity in his men. These methods, the experimenter explained to him, might include words of encouragement, reprimands, promises of pay increase, and general advice on construction. He would speak to his workers by means of a one-way communication device comprised of a microphone and light signal for contacting individual workers. Communications allegedly coming from the various workers consisted of preprogrammed, play-acted tape recordings. The explanation presented to supervisors for not being permitted to see the workers was that the impressions they would acquire by seeing individual workers might bias them in their later evaluations. At the end of a trial the supervisor heard voiced comments from individual men, and then the experimenter brought in a count of each worker's output. Before and during every trial the supervisor had in front of him a fully assembled illustration of the model on which the men were currently working and also a fabricated set of norms (based on actual pretesting). These norms were expressed as performance percentile scores for college students. The student supervisor understood that workers had been promised a base pay of $2 for their participation but that he as supervisor could administer a 25¢ pay increase or decrease at the end of a given trial.

There were two conditions in the experiment, one with Man C acting as an ingratiator and the other with Man C assuming a neutral, noningratiating role. All three workers maintained roughly an average performance throughout both conditions. Number of words spoken per man was also equalized across workers and experimental treatments.

Table 1
Mean Performance Evaluations, Pay Increases, and Liking Ratings Given the Ingratiating Worker

Level of *n* Power in supervisor	Performance		Pay		Liking	
	Ingratiator	Neutral worker	Ingratiator	Neutral worker	Ingratiator	Neutral worker
High						
M	29.3_a	22.1_b	50.0	35.0	6.8	5.7
SD	4.2	4.8	19.9	27.4	1.7	1.8
Low						
M	24.2_b	23.0_b	37.5	31.3	6.2	5.9
SD	4.9	3.9	26.3	24.2	1.9	2.0

Note. Means with differing subscripts differ significantly from each other, $p < .01$.

Twenty of the student supervisors assigned to the ingratiator condition had scored in the top third of the need for power distribution, and 20 had scored in the bottom third. Of people assigned to the noningratiator condition, 20 had likewise obtained high scores on the power motive, and 20 were low. The ingratiator, Man C, established his style of relating to the supervisor at the end of Trial 2 by saying, "You know, I really like your approach. I can see you're gonna be a good supervisor." Trial 4 produced the remark, "Personally, I think you're doin' a great job." Man C completed Trial 5 on an equally complimentary note by commenting, "You've done pretty good." All of these utterances were illustrative of the form of ingratiation that Jones (1964) has designated as "complimentary other-enhancement."

Other communications by Man C and the remaining workers were neutral both in content and in emotional tone. At the conclusion of Trial 2, for example, Man A blandly proclaimed, "Not much to say this time, I guess." Man B said, "Well, so much for this job. What's next?"

When the supervisor had finished directing the work activities of his crew, the experimenter led him to another room and requested that he evaluate the performance of each worker on four 9-point scales: (a) worker's ability, (b) worker's overall worth to the company, (c) willingness to rehire worker for a second experiment, and (d) recommendation that the worker be promoted to supervisor in a future experiment. For purposes of analysis, these four scale scores were summated to obtain a single overall score. The student supervisor also completed ratings on how much he would like the worker as a personal friend (liking score) and how much he thought he had influenced the performance of each (influence score).

The experimenter then closely interrogated the supervisor to determine whether he believed there were no workers in the next room. Six supervisors so stated and were dropped from further data analysis. Eighty subjects remained, 20 in each of four groups as previously indicated. Another function of the postexperimental interview was to explain to subjects the details and underlying rationale of the study and then to swear them to secrecy.

Results

The first and major hypothesis of the study predicted that student supervisors scoring high on the power motive would bestow disproportionately high rewards upon the ingratiator. The relevant data appear in Table 1. Supervisory reward could take three different forms—performance ratings, pay increase, and liking. By all three forms of reward, persons scoring high on the power motive were found to confer higher rewards upon the ingratiator than were those scoring low. Moreover, persons high on need for power favored the ingratiator more than their counterparts in the control condition benefited Man C who was not an ingratiator. Since reward could take any of these three forms, the decision was made to perform a multivariate analysis of variance initially and then, as recommended by Hummel and Sligo (1971), to follow with univariate analyses of variance of the three variables taken separately to trace the source of multivariate effects. Overall, considering the three dependent variables together, there was a main effect for condition, $F(1, 76) = 6.20$, $p < .001$, but not for *n* Power, $F(1, 76) = 1.88$, *ns*. Supervisors distributed more of various forms of reward to Man C who was an ingratiator than their counterparts in the control group awarded to Man C who was not an ingratiator. Supervisors high in power motivation did not generally give greater reward to

Man C than did those low in power motivation. A significant interaction effect was obtained, however, $F(1, 76) = 3.23$, $p < .05$, indicating that high-scoring supervisors dispensed greater reward to Man C, who was an ingratiator, than did low-scoring supervisors, whereas high- and low-scoring supervisors treated Man C of the control condition, who was not an ingratiator, about the same. Analysis of the three dependent variables individually revealed that the performance ratings alone accounted for most of the multivariate effect just described. There was a main effect for *n* Power, $F(1, 76) = 4.32$, $p < .05$, for condition, $F(1, 76) = 17.89$, $p < .001$, and for the interaction as well, $F(1, 76) = 8.87$, $p < .01$. Specifically, there was a pronounced tendency for supervisors high in need for power to evaluate very favorably Man C who was an ingratiator. These same supervisors did not evaluate Man C as favorably in the control condition when he was not an ingratiator. Supervisors low in power motivation completed roughly similar performance appraisals on Man C regardless of whether or not he was an ingratiator, and in neither case did these appraisals approach those that high-scoring subjects gave Man C when he was an ingratiator. There was in addition a marginally significant main effect for condition in relation to pay increase, $F(1, 76) = 3.74$, $p < .06$, indicating a tendency for supervisors to award greater pay increase to Man C when he was an ingratiator. None of the remaining univariate analyses done in relation to pay increase or liking proved to be significant.

Post hoc comparisons were made by means of Tukey's honestly significant differences (HSD) test, and Table 1 portrays those results. Student supervisors high on *n* Power clearly gave higher evaluations to the ingratiator than were granted by supervisors to Man C in other conditions of the experiment.

The interaction effect for performance appraisal is illustrated in Figure 1. Supervisors high and low on *n* Power evaluated Man C about the same when he was neutral and noningratiating in his manner, but when Man C assumed the role of ingratiator, supervisors high in power motivation rated his performance substantially higher than did those low on *n* Power.

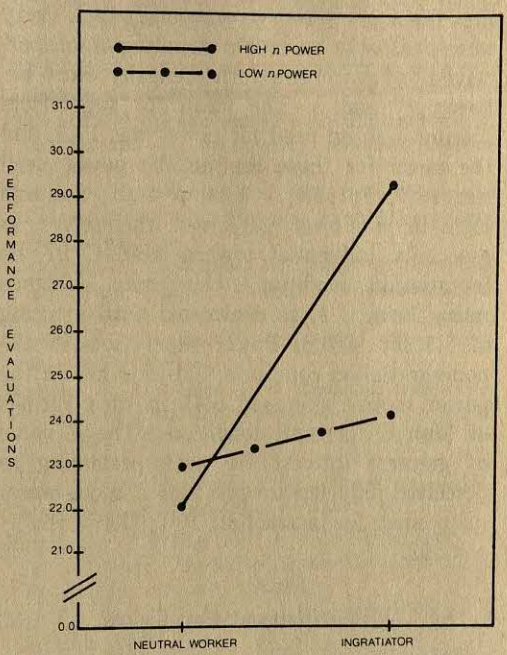

Figure 1. Effects of *n* Power and ingratiation on performance evaluations by student supervisors.

The second hypothesis was that high *n* Power supervisors would make greater distinctions between Man A and Man B, the two neutral workers, in performance appraisal and total amounts of pay increase they awarded. Data were collapsed across the ingratiator and noningratiator conditions so that all 40 supervisors high on the power motive were compared against the 40 who were low. Not only did the performance appraisal data fail to confirm the hypothesis, but they actually indicated a slight but nonsignificant trend in the direction contrary to prediction. Supervisors high in *n* Power gave performance evaluations to Man A and Man B that differed by a mean of 4.1, whereas the corresponding figure for supervisors low on *n* Power was 5.7. For pay increases, the figures were 13.1 and 12.5, respectively, again a nonsignificant difference.

Perceived supervisory influence was the focus of the last hypothesis. A "total influence score" was computed by tallying across workers figures circled to represent how responsive supervisors believed the various workers were to the supervisor's efforts to influence their performance. Individual rat-

ings ran from 9 (very responsive) to 1 (very unresponsive); so scores denoting total perceived influence could theoretically vary between 27 and 3. The mean for supervisors scoring high on need for power was 17.3, and the mean for those low on the power need was 15.9, $F(1, 78) = 4.44$, $p < .05$. Subjects high in *n* Power perceived themselves as especially influential toward Man C in the ingratiation condition, their mean influence rating being 7.3, as contrasted with a rating of 5.5 for high *n* Power supervisors in the noningratiation condition. Subjects low in the power motive averaged 6.45 in their ratings of Man C for both conditions. The *F* value of greatest interest for data pertaining to perceived influence toward Man C alone was a main effect for interaction, $F(1, 78) = 16.72$; $p < .02$.

Discussion and Conclusions

The major findings of the present experiment accord well with Winter's conceptualization of need for power. Ingratiation, even though it is not sincere, may provide the target person with the overt appearance of recognition for exercise of power-oriented behaviors, the quest for which, Winter believes, is integral to the personality of persons high in power motivation. These features were unmistakably present in the personality of Woodrow Wilson, one of the presidents whose inaugural address Winter scored as reflecting high power imagery. Consider the observations of Wilson's biographers, George and George (1956):

> All of Wilson's close friends—the men, the women, the professors, the politicians, the socialites—shared one characteristic: they were, or at least had to seem to him to be, *uncritical* admirers of the man and of everything he did. Intellectual disagreement or the feeling that a friend disapproved of some project he had in hand aroused intolerable anxieties. . . . To . . . Wilson, identity of opinion and love were inseparably linked. He never learned that he and a friend could disagree and still retain a mutual affection. To him, if a friend disagreed with him about a matter of importance, it signified that the friend no longer cared for him. (pp. 31–32)

Maccoby (1976) makes a similar point when he observes that power-seeking managers "must surround themselves with admirers, and admiration becomes a drug for them. . ." (p. 199).

Horney (1937) has argued that the quest for power arises from thwarted childhood needs for parental affection. As viewed in this perspective, ingratiation may have brought reassurance to power-motivated student supervisors that they were worthy of respect or possibly even affection.

Belief by the supervisor high in *n* Power that he influenced the behavior of subordinates may have served a function similar to that provided by ingratiation from subordinates. Both events create a cognitive awareness that one has had an impact on others, that one has elicited a response from them that is contingent upon one's own actions. It is that very awareness, according to our foregoing theoretical analysis, which power-oriented persons especially crave.

Student supervisors high on the power motive, it will be recalled, did not reveal any significant tendency to grant high pay increases to an ingratiating subordinate. The pay increase measure probably was not highly sensitive to differences in response from workers, because it was not until the end of the session that Man C had thoroughly established himself as an ingratiator in the critical condition of the experiment. By that time, much of the opportunity for dispensing differential reward in the form of pay increase had passed.

McClelland and Burnham (1976) found that managers high in power motivation tended to foster organizational climates that were maximally conducive to high work performance. It should be noted, however, that McClelland and Burnham regarded as critical to their analysis high *n* Power scores accompanied by low scores on *n* Affiliation; so their measure was not strictly comparable to the one devised by Winter. Winter (1973) did find, however, that persons aspiring to careers in management scored high in *n* Power.

The McClelland and Burnham finding that managers high in power motivation perform well in the sense of creating an optimal organizational climate lends plausibility to the argument that perhaps high *n* Power people may be susceptible to flattery because, on the basis of past experience with their own per-

formance, they have discovered that they actually *do* make good decisions and perform well at tasks they undertake. Thus the ingratiator may more easily be believed, since the information he transmits accords well with earlier evidence the high *n* Power person has about himself.

An interesting parallel occurs between the present conclusions concerning *n* Power and previous findings on self-confidence. Goodstadt and Kipnis (1970) reported that persons high in self-confidence, as contrasted with persons low in self-confidence, exercised more influence over subordinates, whereas Kipnis and Vanderveer (1971) found persons high in self-confidence to be more susceptible to the ingratiator's flattery. What correlation exists between *n* Power and self-confidence is not known, although it is apparent that McClelland and Burnham (1976) see a heightening of self-confidence as a consequence likely to result from their training program for promoting greater power motivation among managers.

These findings can be viewed as an illustration of the joint interaction of personality and situation as codeterminants of social behavior, especially when contrasted with previous inquiries into use of power. One is reminded of Kurt Lewin's classic formulation, $B = f(P,E)$, which stated that behavior is some interactive function of both person and environment.

The central message of the present investigation for those interested in managerial training is clear. Persons best equipped by personality to influence and control others may not be well suited to evaluate human performance. Training programs should perhaps stress the discontinuity between the control and judgmental functions of management, emphasizing greatly the need for objective systems of performance appraisal.

Biased Assimilation and Attitude Polarization: The Effects of Prior Theories on Subsequently Considered Evidence

Charles G. Lord, Lee Ross, and Mark R. Lepper
Stanford University

People who hold strong opinions on complex social issues are likely to examine relevant empirical evidence in a biased manner. They are apt to accept "confirming" evidence at face value while subjecting "disconfirming" evidence to critical evaluation, and as a result to draw undue support for their initial positions from mixed or random empirical findings. Thus, the result of exposing contending factions in a social dispute to an identical body of relevant empirical evidence may be not a narrowing of disagreement but rather an increase in polarization. To test these assumptions and predictions, subjects supporting and opposing capital punishment were exposed to two purported studies, one seemingly confirming and one seemingly disconfirming their existing beliefs about the deterrent efficacy of the death penalty. As predicted, both proponents and opponents of capital punishment rated those results and procedures that confirmed their own beliefs to be the more convincing and probative ones, and they reported corresponding shifts in their beliefs as the various results and procedures were presented. The net effect of such evaluations and opinion shifts was the postulated increase in attitude polarization.

The human understanding when it has once adopted an opinion draws all things else to support and agree with it. And though there be a greater number and weight of instances to be found on the other side, yet these it either neglects and despises, or else by some distinction sets aside and rejects, in order that by this great and pernicious predetermination the authority of its former conclusion may remain inviolate. (Bacon, 1620/1960)

Often, more often than we care to admit, our attitudes on important social issues reflect only our preconceptions, vague impressions, and untested assumptions. We respond to social policies concerning compensatory education, water fluoridation, or energy conservation in terms of the symbols or metaphors they evoke (Abelson, 1976; Kinder & Kiewiet, Note 1) or in conformity with views expressed by opinion leaders we like or respect (Katz, 1957). When "evidence" is brought to bear it is apt to be incomplete, biased, and of marginal probative value—typically, no more than a couple of vivid, concrete, but dubiously representative instances or cases (cf. Abelson, 1972; Nisbett & Ross, in press). It is unsurprising, therefore, that important social issues and policies generally prompt sharp disagreements, even among highly concerned and intelligent citizens, and that such disagreements often survive strenous attempts at resolution through discussion and persuasion.

An interesting question, and one that prompts the present research, involves the consequences of introducing the opposing factions to relevant and objective data. This question seems particularly pertinent for contemporary social scientists, who have frequently called for "more empirically based" social decision making (e.g., Campbell, 1969). Very likely, data providing consistent and

unequivocal support for one or another position on a given issue can influence decision makers and, with sufficiently energetic dissemination, public opinion at large. But what effects can be expected for more mixed or inconclusive evidence of the sort that is bound to arise for most complex social issues, especially where full-fledged experiments yielding decisive and easy-to-generalize results are a rarity? Logically, one might expect mixed evidence to produce some moderation in the views expressed by opposing factions. At worst, one might expect such inconclusive evidence to be ignored.

The present study examines a rather different thesis—one born in an analysis of the layperson's general shortcomings as an intuitive scientist (cf. Nisbett & Ross, in press; Ross, 1977) and his more specific shortcomings in adjusting unwarranted beliefs in the light of empirical challenges (cf. Ross, Lepper, & Hubbard, 1975). Our thesis is that belief polarization will *increase*, rather than decrease or remain unchanged, when mixed or inconclusive findings are assimilated by proponents of opposite viewpoints. This "polarization hypothesis" can be derived from the simple assumption that data relevant to a belief are not processed impartially. Instead, judgments about the validity, reliability, relevance, and sometimes even the meaning of proffered evidence are biased by the apparent consistency of that evidence with the perceiver's theories and expectations. Thus individuals will dismiss and discount empirical evidence that contradicts their initial views but will derive support from evidence, of no greater probativeness, that seems consistent with their views. Through such biased assimilation even a random set of outcomes or events can appear to lend support for an entrenched position, and both sides in a given debate can have their positions bolstered by the same set of data.

As the introductory quotation suggests, the notions of biased assimilation and resulting belief perseverance have a long history. Beyond philosophical speculations and a wealth of anecdotal evidence, considerable research attests to the capacity of preconceptions and initial theories to bias the consideration of subsequent evidence, including work on classic Einstellung effects (Luchins, 1942, 1957), social influence processes (Asch, 1946), impression formation (e.g., Jones & Goethals, 1971), recognition of degraded stimuli (Bruner & Potter, 1964), resistance to change of social attitudes and stereotypes (Abelson, 1959; Allport, 1954), self-fulfilling prophecies (Merton, 1948; Rosenhan, 1973; Snyder, Tanke, & Berscheid, 1977), and the persistence of "illusory correlations" (Chapman & Chapman, 1967, 1969). In a particularly relevant recent demonstration, Mahoney (1977) has shown that trained social scientists are not immune to theory-based evaluations. In this study, professional reviewers' judgments about experimental procedures and resultant publication recommendations varied dramatically with the degree to which the findings of a study under review agreed or disagreed with the reviewers' own theoretical predilections.

Thus, there is considerable evidence that people tend to interpret subsequent evidence so as to maintain their initial beliefs. The biased assimilation processes underlying this effect may include a propensity to remember the strengths of confirming evidence but the weaknesses of disconfirming evidence, to judge confirming evidence as relevant and reliable but disconfirming evidence as irrelevant and unreliable, and to accept confirming evidence at face value while scrutinizing disconfirming evidence hypercritically. With confirming evidence, we suspect that both lay and professional scientists rapidly reduce the complexity of the information and remember only a few well-chosen supportive impressions. With disconfirming evidence, they continue to reflect upon any information that suggests less damaging "alternative interpretations." Indeed, they may even come to regard the ambiguities and conceptual flaws in the data *opposing* their hypotheses as somehow suggestive of the fundamental *correctness* of those hypotheses. Thus, completely inconsistent or even *random* data—when "processed" in a suitably biased fashion—can maintain or even reinforce one's preconceptions.

The present study was designed to examine both the biased assimilation processes that

may occur when subjects with strong initial attitudes are confronted with empirical data concerning a controversial social issue and the consequent polarization of attitudes hypothesized to result when subjects with differing initial attitudes are exposed to a common set of "mixed" experimental results. The social controversy chosen for our investigation was the issue of capital punishment and its effectiveness as a deterrent to murder. This choice was made primarily because the issue is the subject of strongly held views that frequently do become the target of public education and media persuasion attempts, and has been the focus of considerable social science research in the last twenty years. Indeed, as our basic hypothesis suggests, contending factions in this debate often cite and derive encouragement from the same body of inconclusive correlational research (Furman v. Georgia, 1972; Sarat & Vidmar, 1976; Sellin, 1967).

In the present experiment, we presented both proponents and opponents of capital punishment first with the results and then with procedural details, critiques, and rebuttals for two studies dealing with the deterrent efficacy of the death penalty—one study confirming their initial beliefs and one study disconfirming their initial beliefs. We anticipated biased assimilation at every stage of this procedure. First, we expected subjects to rate the quality and probative value of studies confirming their beliefs on deterrent efficacy more highly than studies challenging their beliefs. Second, we anticipated corresponding effects on subjects' attitudes and beliefs such that studies confirming subjects' views would exert a greater impact than studies disconfirming those views. Finally, as a function of these assimilative biases, we hypothesized that the net result of exposure to the conflicting results of these two studies would be an increased polarization of subjects' beliefs on deterrent efficacy and attitudes towards capital punishment.

Method

Subjects

A total of 151 undergraduates completed an in-class questionnaire that included three items on capital punishment. Two to four weeks later, 48 of these students were recruited to participate in a related experiment as partial fulfillment of a course requirement. Twenty-four were "proponents" who favored capital punishment, believed it to have a deterrent effect, and thought most of the relevant research supported their own beliefs. Twenty-four were "opponents" who opposed capital punishment, doubted its deterrent effect, and thought that the relevant research supported *their* views.

Procedure

Upon entering the experiment, mixed groups of proponents and opponents were seated at a large table. The experimenter, blind to subjects' attitudes, told them that they would each be asked to read 2 of 20 randomly selected studies on the deterrent efficacy of the death penalty and asked them to use their own "evaluative powers" in thinking about what the author(s) of the study did, what the critics had to say, and whether the research provided support for one side or the other of this issue.

The experimenter next showed subjects a set of 10 index cards, each containing a brief statement of the results of a single study. Each subject was asked to choose one card and read it silently. In reality, all 10 cards in any one session were identical, providing either prodeterrent information, for example:

> Kroner and Phillips (1977) compared murder rates for the year before and the year after adoption of capital punishment in 14 states. In 11 of the 14 states, murder rates were *lower after* adoption of the death penalty. This research supports the deterrent effect of the death penalty.

or antideterrent information, for example:

> Palmer and Crandall (1977) compared murder rates in 10 pairs of neighboring states with different capital punishment laws. In 8 of the 10 pairs, murder rates were *higher* in the state *with* capital punishment. This research opposes the deterrent effect of the death penalty.

To control for order effects, half of the proponents and half of the opponents saw a "prodeterrence" result first, and half saw an "antideterrence" result first. The studies cited, although invented specifically for the present study, were characteristic of research found in the current literature cited in judicial decisions.

After reading one of these "result cards," subjects answered two sets of questions, on 16-point scales, about changes in their attitudes toward capital punishment (from −8 = more opposed, to 8 = more in favor) and their beliefs about the deterrent efficacy of the death penalty (from −8 = *less* belief that capital punishment has a deterrent effect, to 8 = *more* belief in the deterrent effect). One set of questions examined change occasioned by the single piece of information they had just finished reading; a second set of questions assessed the cumulative change

produced by all of the materials read since the start of the experiment.[1]

Next the experimenter distributed detailed research descriptions bearing code letters corresponding to those on the result cards. The descriptions gave details of the researchers' procedure, reiterated the results, mentioned several prominent criticisms of the study "in the literature," listed the authors' rebuttals to some of the criticisms and depicted the data both in table form and graphically. After reading this more detailed description and critique of the first study, subjects were asked to judge how well or poorly the study had been conducted (from $-8 =$ very poorly done, to $8 =$ very well done), and how convincing the study seemed as evidence on the deterrent efficacy of capital punishment (from $-8 =$ completely unconvincing, to $8 =$ completely convincing).[2] Following this evaluation, subjects were asked to write why they thought the study they had just read did or did not support the argument that capital punishment is a deterrent to murder, and then to answer a second set of attitude and belief change questions on the effects of the description alone and the effects of all experimental materials (i.e., the results and subsequent description and critique) up to that point in time.

Following completion of these questions, the entire procedure was repeated, with a second fictitious study reporting results opposite to those of the first. Again, subjects initially received only a brief description of the results of this second study but were then provided with a detailed presentation of the procedure, results, and critiques. As before, subjects were asked to evaluate both the impact of each single piece of evidence and the impact of all experimental materials up to that point in the experiment on their attitudes toward capital punishment and their beliefs concerning its deterrent efficacy.

To control for possible differences in the inherent plausibility of the two studies, two sets of materials were employed that interchanged the ostensible results of the two invented experiments. The overall design was thus completely counterbalanced with respect to subjects' initial attitudes, order of confirming vs. disconfirming evidence, and the association of the "before–after" vs. "adjacent states" designs with positive or negative results.[3] At the end of the procedure, subjects were carefully debriefed concerning the fictitious nature of the studies and were asked not to reveal this deception to others. In addition to insuring that subjects understood the fictional nature of the experimental materials, this debriefing included discussion of the processes underlying the assimilation of evidence to previous theories and reassurance that a skeptical reaction to poorly designed research is often a praiseworthy cognitive response.

Results

Evaluations of the Two Studies

Our first hypothesis was that subjects holding different initial positions would differentially evaluate the quality and "convincingness" of the same empirical studies and findings. The relevant evaluations, presented in Table 1, revealed strong support for the hypothesized bias in favor of the study that confirmed subjects' initial attitudes.

A two-way analysis of variance (Initial Attitude × Order of Presentation) on the differences between ratings of convincingness of the prodeterrence and antideterrence studies yielded only a main effect of initial attitude, $F(1, 44) = 32.07$, $p < .001$. Proponents

---

[1] Since most of our subjects had reported initial positions at, or very close to, the ends of the attitude and belief scales used for selection purposes, our initial plan to assess attitude polarization—in terms of difference scores assessing changes in subjects' attitudes and beliefs on these same scales from these initial measures to the completion of the experiment—proved impossible. As a substitute, we employed three sorts of measures to assess attitude change. First, we asked subjects, after each new piece of information, to indicate any changes in their attitudes and beliefs occasioned by that single piece of information. Second, we asked subjects, at these same points, to report on "cumulative" changes in their attitudes and beliefs since the start of the experiment. Third, subjects were asked to keep "running records" of their attitudes and beliefs on enlarged versions of the scales initially used for selection purposes. Although all of these measures individually raise some problems, the congruence of data across these different measurement devices gives us some confidence concerning the results reported. Indeed, because the results obtained on the "running record" measure so completely parallel the findings obtained on the cumulative change question depicted in Figures 1 and 2, in terms of both the array of means and the obtained significance levels, the data from this measure will not be reported separately.

[2] Subjects were also asked, at this point, whether they thought the researchers had favored or opposed the death penalty and whether they thought an unbiased consideration should lead one to treat the study as evidence for or against capital punishment. Analyses on the first question showed only that subjects believed the researchers' attitudes to coincide with their stated results. Analyses on the second question proved wholly redundant with those presented for the "convincingness" and "well done" questions.

[3] Preliminary analyses were conducted to see if the particular association of positive versus negative results with either the before–after or adjacent-states designs would affect the results obtained. There were no significant effects or interactions involving this variation in stimulus materials; hence, the data were collapsed across this factor.

Table 1
Evaluations of Prodeterrence and Antideterrence Studies by Proponents and Opponents of Capital Punishment

Study	Proponents	Opponents
Mean ratings of how well the two studies had been conducted		
Prodeterrence	1.5	−2.1
Antideterrence	−1.6	− .3
Difference	3.1	−1.8
Mean ratings of how convincing the two studies were as evidence on the deterrent efficacy of capital punishment		
Prodeterrence	1.4	−2.1
Antideterrence	−1.8	.1
Difference	3.2	−2.2

Note. Positive numbers indicate a positive evaluation of the study's convincingness or procedure. Negative numbers indicate a negative evaluation of the study's convincingness or procedure.

regarded the prodeterrence study as significantly more convincing than the antideterrence study, $t(23) = 5.18$, $p < .001$,[4] regardless of whether it was the "before–after" design that suggested the efficacy of capital punishment and the "adjacent states" design that refuted it, or vice versa. Opponents, by contrast, regarded the prodeterrence study as significantly less convincing than the antideterrence study, $t(23) = -3.02$, $p < .01$, again irrespective of which research design was purported to have produced which type of results. The same was true of the difference between ratings of how well done the two studies had been, $F(1, 44) = 33.52$, $p < .001$.[5] As above, proponents found the prodeterrence study to have been better conducted than the antideterrence study, $t(23) = 5.37$, $p < .001$, whereas opponents found the prodeterrence study to have been less well conducted, $t(23) = -2.80$, $p < .05$. As one might expect, the correlation between the "convincingness" and "well done" questions was substantial, $r = .67$, $p < .001$.

These differing opinions of the quality of the two studies were also reflected in subjects' written comments. At the risk of opening ourselves to a charge of "biased assimilation," we present a set of subjects' comments—selected for dramatic effect but not unrepresentative in content—in Table 2. As these comments make clear, the same study can elicit entirely opposite evaluations from people who hold different initial beliefs about a complex social issue. This evidence of bias in subjects' evaluations of the quality and convincingness of the two studies is consistent with the biased assimilation hypothesis and sets the stage for testing our further predictions concerning attitude and belief polarization.

Overall Attitude Polarization

Given such biased evaluations, our primary hypothesis was that exposure to the "mixed"[6] data set comprised by the two studies would result in a further polarization of subjects' attitudes and beliefs rather than the convergence that an impartial consideration of these inconclusive data might warrant. To test this hypothesis requires a consideration

[4] All p values reported in this article are based on two-tailed tests of significance.

[5] In order to examine possible main effects of either study direction or initial attitude on subjects' ratings of how convincing and how well done the studies were—findings that would not be portrayed in the difference score analysis reported—a three-way analysis of variance (Initial Attitude × Order of Presentation × Direction of Study) was also performed. There were no main effects of study direction on either measure. A main effect of initial attitude—indicating that opponents evaluated the total set of evidence more negatively than did proponents—proved significant for the "well done" question, $F(1, 44) = 4.69$, $p < .05$, but not for the "convincing" question, $F(1, 44) = 1.53$, *ns*.

[6] The term *mixed*, we should emphasize, refers to the fact that one study yielded evidence confirming the deterrent efficacy of the death penalty, whereas the other study yielded evidence disconfirming such efficacy (with appropriate counterbalancing of purported procedures and purported results). Subjects, regardless of initial position, clearly recognized this discrepancy between results, as will be apparent in our analyses of their responses to the simple statements of the study's main findings. We do not mean to imply that the subjects "phenomenologically" judged the two studies to be of equal probative value; indeed, as indicated in the preceding discussion, identical procedures were clearly judged to differ in their probativeness depending on the congruity between the study's outcomes and the subject's initial beliefs.

Table 2
Selected Comments on Prodeterrence and Antideterrence Studies by Proponents and Opponents of Capital Punishment

Subject	Comments on Prodeterrence study	Comments on Antideterrence study
	Set 1 materials	
S8 Proponent	"It does support capital punishment in that it presents facts showing that there is a deterrent effect and seems to have gathered data properly."	"The evidence given is relatively meaningless without data about how the overall crime rate went up in those years."
S24 Proponent	"The experiment was well thought out, the data collected was valid, and they were able to come up with responses to all criticisms."	"There were too many flaws in the picking of the states and too many variables involved in the experiment as a whole to change my opinion."
S35 Opponent	"The study was taken only 1 year before and 1 year after capital punishment was reinstated. To be a more effective study they should have taken data from at least 10 years before and as many years as possible after."	"The states were chosen at random, so the results show the average effect capital punishment has across the nation. The fact that 8 out of 10 states show a rise in murders stands as good evidence."
S36 Opponent	"I don't feel such a straightforward conclusion can be made from the data collected."	"There aren't as many uncontrolled variables in this experiment as in the other one, so I'm still willing to believe the conclusion made."
	Set 2 materials	
S14 Proponent	"It shows a good direct comparison between contrasting death penalty effectiveness. Using neighboring states helps to make the experiment more accurate by using similar locations."	"I don't think they have complete enough collection of data. Also, as suggested, the murder rates should be expressed as percentages, not as straight figures."
S15 Proponent	"It seems that the researchers studied a carefully selected group of states and that they were careful in interpreting their results."	"The research didn't cover a long enough period of time to prove that capital punishment is not a deterrent to murder."
S25 Opponent	"The data presented are a randomly drawn set of 10. This fact seems to be the study's biggest problem. Also many other factors are not accounted for which are very important to the nature of the results."	"The murder rates climbed in all but two of the states after new laws were passed and no strong evidence to contradict the researchers has been presented."
S38 Opponent	"There might be very different circumstances between the sets of two states, even though they were sharing a border."	"These tests were comparing the same state to itself, so I feel it could be a fairly good measure."

of subjects' final attitudes, after exposure to both studies and related critiques and rebuttals, relative to the start of the experiment.

The relevant data provide strong support for the polarization hypothesis. Asked for their final attitudes relative to the experi-

Table 3
Mean Attitude and Belief Changes for a Single Piece of Information

Issue and study	Initial attitudes: Proponents	Initial attitudes: Opponents
Results only		
Capital punishment		
Prodeterrence	1.3	0.4
Antideterrence	−0.7	−0.9
Combined	0.6	−0.5
Deterrent efficacy		
Prodeterrence	1.9	0.7
Antideterrence	−0.9	−1.6
Combined	1.0	−0.9
Details, data, critiques, rebuttals		
Capital punishment		
Prodeterrence	0.8	−0.9
Antideterrence	0.7	−0.8
Combined	1.5	−1.7
Deterrent efficacy		
Prodeterrence	0.7	−1.0
Antideterrence	0.7	−0.8
Combined	1.4	−1.8

Note. Positive numbers indicate a more positive attitude or belief about capital punishment and its deterrent effect. Negative numbers indicate a more negative attitude or belief about capital punishment and its deterrent effect.

ment's start, proponents reported that they were *more* in favor of capital punishment, $t(23) = 5.07$, $p < .001$, whereas opponents reported that they were *less* in favor of capital punishment, $t(23) = -3.34$, $p < .01$. In a two-way analysis of variance (Initial Attitude × Order of Presentation), the effect of initial attitude was highly significant, $F(1, 44) = 30.06$, $p < .001$, and neither the order effect nor the interaction approached significance. Similar results characterized subjects' beliefs about deterrent efficacy. Proponents reported greater belief in the deterrent effect of capital punishment, $t(23) = 4.26$, $p < .001$, whereas opponents reported less belief in this deterrent effect, $t(23) = -3.79$, $p < .001$. Final attitudes toward capital punishment and beliefs concerning deterrent efficacy were highly correlated, $r = .88$, $p < .001$.

Such results provide strong support for the main experimental hypothesis that inconclusive or mixed data will lead to increased polarization rather than to uncertainty and moderation. Moreover, the degree of polarization shown by individual subjects was predicted by differences in subjects' willingness to be less critical of procedures yielding supportive evidence than of procedures yielding nonsupportive evidence. Significant correlations were found between overall attitude change regarding capital punishment and differences in ratings of both how convincing, $r = .56$, $p < .001$, and how well done, $r = .56$, $p < .001$, the studies were. Overall changes in beliefs in deterrent efficacy produced comparable correlations of .53 and .57, both $ps < .001$.

Components of Attitude Polarization

In view of this strong evidence of overall attitude polarization, it is worth examining the course of attitude polarization as subjects' opinions were successively assessed after exposure to the first study, the details and critiques of the first study, the results of the second study, and the details and critiques of the second study. At each stage, it will be recalled, subjects were asked about the impact of the single piece of information they had just considered and the cumulative impact of all information presented to that point. Let us first examine the reported effects of single segments of evidence and then the effects of accumulated evidence over time.

Effect of Exposure to the Results of Each Study

Considering the result cards as single pieces of evidence, both proponents and opponents reported shifting their attitudes in the direction of the stated results for both the pro-deterrence, $t(47) = 4.67$, $p < .001$, and anti-deterrence, $t(47) = -5.15$, $p < .001$, studies. As shown in the top half of Table 3, however, subjects' responses to the two studies also varied with initial attitude. Proponents tended to be influenced more by the prodeterrence study and opponents more by the anti-deterrence study. Thus a two-way analysis of variance (Initial Attitude × Order of Pre-

sentation) on combined change from the two result cards considered individually yielded only a main effect of initial attitude for both attitudes toward the death penalty, $F(1, 44) = 6.35$, $p < .02$,[7] and beliefs about its deterrent effect, $F(1, 44) = 10.37$, $p < .01$. Interestingly, the analysis of beliefs regarding deterrent efficacy also showed an unanticipated interaction effect, $F(1, 44) = 7.48$, $p < .01$, with proponents showing a differential response to results alone regardless of order of presentation but opponents showing a differential response to results alone only when the confirming study was presented first.

Effect of Exposure to Procedures and Data, Critiques and Rebuttals

When provided with a more detailed description of the procedures and data, together with relevant critiques and authors' rebuttals, subjects seemed to ignore the stated results of the study. As shown in the bottom half of Table 3, both proponents and opponents interpreted the additional information, relative to the results alone, as strongly supporting their own initial attitudes. Detailed descriptions of either the prodeterrence or the antideterrence study, with accompanying critiques, caused proponents to favor capital punishment more and believe in its deterrent efficacy more, but caused opponents to oppose capital punishment more and believe in its deterrent efficacy less. A two-way analysis of variance (Initial Attitude × Order of Presentation) on attitude change for the two descriptions combined yielded only a significant main effect of initial attitude for both the capital punishment issue, $F(1, 44) = 28.10$, $p < .001$, and the deterrent efficacy question, $F(1, 44) = 26.93$, $p < .001$.

Changes in Attitudes Across Time

Subjects' reported changes in attitudes and beliefs, relative to the start of the experiment, following exposure to each of the four separate pieces of information are depicted in Figure 1 for attitudes concerning capital punishment and in Figure 2 for beliefs concerning deterrent efficacy. These data, portrayed separately for subjects who received first either the prodeterrence study or the antideterrence study, provide a more detailed view of the attitude polarization process. They allow, as well, an examination of the hypothesized "rebound effect," that the provision of any plausible reason for discounting data that contradict one's preconceptions will eliminate the effects that mere knowledge of those data may have produced.

The existence of such a "rebound effect" is obvious from examination of these figures. Whether they encountered the disconfirming result first or second, both proponents and opponents seemed to be swayed momentarily by this evidence, only to revert to their former attitudes and beliefs (and in 23% of the individual cases, to even more extreme positions) after inspecting the procedural details and data, and the critiques and rebuttals found in the literature. Across all subjects, this rebound in opinions proved significant for both the capital punishment, $t(47) = 4.43$, $p < .001$, and deterrent efficacy, $t(47) = 4.58$, $p < .001$, issues. By contrast, no compensating rebound effects resulted from reading the descriptions and critiques of studies supporting subjects' initial attitudes, for either capital punishment, $t(47) = .60$, *ns*, or deterrent efficacy, $t(47) = .23$, *ns*.

Discussion

The results of the present experiment provide strong and consistent support for the attitude polarization hypothesis and for the biased assimilation mechanisms postulated to underlie such polarization. The net effect of exposing proponents and opponents of capital punishment to identical evidence—studies ostensibly offering equivalent levels of support and disconfirmation—was to increase further the gap between their views. The mechanisms responsible for this polarization of subjects' attitudes and beliefs were clearly

---

[7] In order to rule out the possibility that direction of study interacted with initial attitude, a three-way analysis of variance (Initial Attitude × Order of Presentation × Direction of Study) was also performed on these data. The relevant interaction term did not approach significance, $F(1, 44) = 1.62$, *ns*.

suggested by correlational analyses. Subjects' decisions about whether to accept a study's findings at face value or to search for flaws and entertain alternative interpretations seemed to depend far less on the particular procedure employed than on whether the study's results coincided with their existing beliefs.

The Normative Issue

It is worth commenting explicitly about the normative status of our subjects' apparent biases. First, there can be no real quarrel with a willingness to infer that studies supporting one's theory-based expectations are more probative than, or methodologically superior to, studies that contradict one's expectations. When an "objective truth" is known or strongly assumed, then studies whose outcomes reflect that truth may reasonably be given greater credence than studies whose outcomes fail to reflect that truth. Hence the physicist would be "biased," but appropriately so, if a new procedure for evaluating the speed of light were accepted if it gave the "right answer" but rejected if it gave the "wrong answer." The same bias leads most of us to be skeptical about reports of miraculous virgin births or herbal cures for cancer, and despite the risk that such theory-based and experience-based skepticism may render us unable to recognize a miraculous event when it occurs, overall we are surely well served by our bias. Our subjects' willingness to impugn or defend findings as a function of their conformity to expectations can, in part, be similarly defended. Only the strength of

their initial convictions in the face of the existing inconclusive social data and arguments can be regarded as "suspect."

Our subjects' main inferential shortcoming, in other words, did not lie in their inclination to process evidence in a biased manner. Willingness to interpret new evidence in the light of past knowledge and experience is essential for any organism to make sense of, and respond adaptively to, its environment. Rather, their sin lay in their readiness to use evidence already processed in a biased manner to bolster the very theory or belief that initially "justified" the processing bias. In so doing, subjects exposed themselves to the familiar risk of making their hypotheses unfalsifiable—a serious risk in a domain where it is clear that at least one party in a dispute holds a false hypothesis—and allowing themselves to be encouraged by patterns of data that they ought to have found troubling. Through such processes laypeople and professional scientists alike find it all too easy to cling to impressions, beliefs, and theories that have ceased to be compatible with the latest and best evidence available (Mahoney, 1976, 1977).

Polarization: Real or Merely Reported?

Before further pursuing the broader implications of the present demonstration, it is necessary to consider an important question raised by our procedure: Did our subjects really show change (i.e., polarization) in their private beliefs about the desirability and deterrent efficacy of capital punishment? Certainly they told us, explicitly, that their

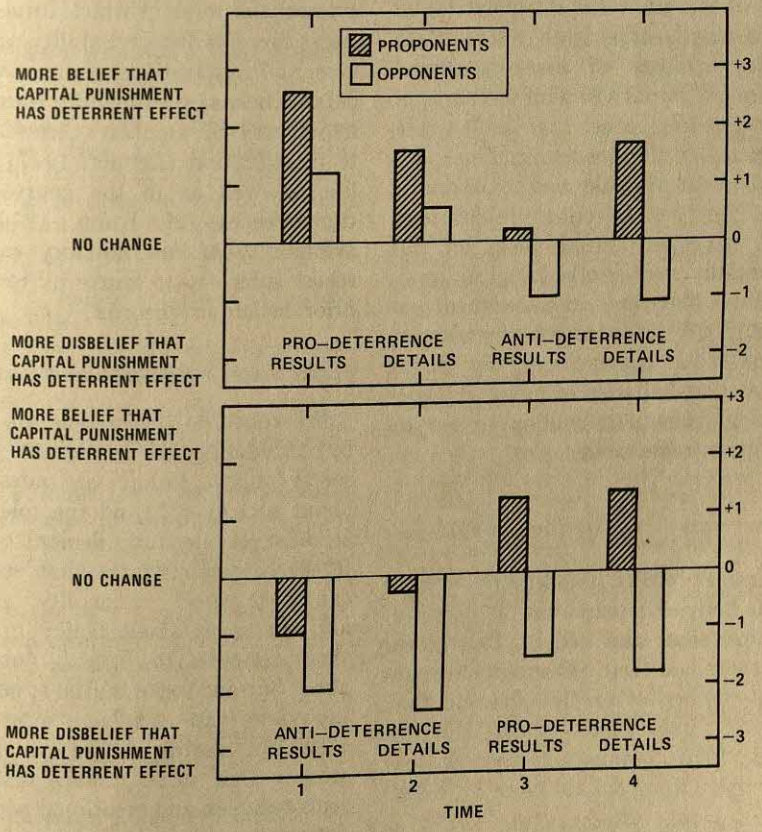

Figure 2. Top panel: Belief changes on capital punishment's deterrent efficacy relative to start of experiment as reported across time by subjects who received prodeterrence study first. Bottom panel: Belief changes on capital punishment's deterrent efficacy relative to start of experiment as reported across time by subjects who received antideterrence study first.

attitudes and beliefs did change after each new piece of evidence was presented, and from the beginning to the end of the experiment. Moreover, they did show a willingness to report a shift in their attitudes in the direction of findings that were contrary to their beliefs, at least until those findings were exposed to methodological scrutiny and possible alternative interpretations. Nevertheless, it could be argued that subjects were not reporting real shifts in attitudes but instead were merely reporting what they believed to be a rational or appropriate response to each increment in the available evidence. Although we believe that it remains an impressive demonstration of assimilation biases to show that contending factions both believe the same data to justify their position "objectively," the potential limitations of the present measures should be kept in mind in evaluating the relationship of this study to prior polarization research. As noted earlier (see Footnote 1) our intended strategy of assessing direct changes from our initial selection measures of attitudes and beliefs, rather than asking subjects to report such changes within the experiment, was neither feasible nor appropriate, given the necessity of selecting subjects with strong and consistent initial views on this issue. Potentially such methodological problems could be overcome in subsequent research through the use of less extreme samples or, perhaps more convincingly, by seeing whether biased assimilation of mixed evidence will make subjects more willing to *act* on their already extreme beliefs.

Belief Perseverance and Attribution Processes

The present results importantly extend the growing body of research on the perseverance of impressions and beliefs. Two of the present authors and their colleagues have now amassed a number of studies showing that, once formed, impressions about the self (Ross et al., 1975; Jennings, Lepper, & Ross, Note 2; Lepper, Ross, & Lau, Note 3), beliefs about other people (Ross et al., 1975), or theories about functional relationships between variables (Anderson, Lepper, & Ross, Note 4) can survive the total discrediting of the evidence that first gave rise to such beliefs. In essence, these prior studies demonstrate that beliefs can survive the complete subtraction of the critical formative evidence on which they were initially based. In a complementary fashion, the present study shows that strongly entrenched beliefs can also survive the addition of nonsupportive evidence.

These findings pose some fundamental questions for traditional attribution models. To the extent that beliefs and impressions can be shown to persevere in the face of subsequent challenging data, we need a "top down" rather than—or perhaps in conjunction with —a "bottom up" approach (cf. Bobrow & Norman, 1975) to the question of how individuals extract meaning from their social environment. Instead of viewing people as impartial, data-driven processors, the present research suggests our models must take into account the ways in which intuitive scientists assess the relevance, reliability, representativeness, and implications of any given sample of data or behavior within the framework of the hypotheses or implicit theories they bring to the situation (Lepper, 1977). In everyday life, as well as in the course of scientific controversies (cf. Kuhn, 1970), the mere availability of contradictory evidence rarely seems sufficient to cause us to abandon our prior beliefs or theories.

Social Science Research and Social Policy

We conclude this article, as we began it, by considering the important links between social policy, public attitudes and beliefs about such policy, and the role of the social scientist. If our study demonstrates anything, it surely demonstrates that social scientists can not expect rationality, enlightenment, and consensus about policy to emerge from their attempts to furnish "objective" data about burning social issues. If people of opposing views can each find support for those views in the same body of evidence, it is small wonder that social science research, dealing with complex and emotional social issues and forced to rely upon inconclusive designs, measures, and modes of analysis, will frequently fuel rather than calm the fires of debate.

Sex Differences in Bystander Intervention in a Theft

William Austin
University of Virginia

A series of studies demonstrated a strong relationship among the situation-defining variable of degree of harm to victim, sexual configuration among participants, and bystanders' willingness to intervene to stop a theft. A pretest showed that a prior verbal commitment was absolutely necessary for intervention. The remaining data showed that high harm to a victim produced a high rate of intervention and showed strong sex differences in helping behavior in low-harm conditions. A high percentage of female bystanders helped in both low- and high-harm situations, whereas frequent helping by males was observed only when harm to the victim was high. Female victims elicited a significantly greater amount of helping, and sex of thief had no effect. A significant sex of bystander, sex of victim, and harm to victim interaction best describes the data. Results are interpreted in terms of different motivational sets held by males and females when they are responsible for the fate of others. Results also support the utility of an interactionist approach to the question of how individual and situational variables influence prosocial action.

In recent years social psychologists have generated a voluminous amount of research on the topic of helping behavior in an attempt to understand the dynamics of prosocial action. Two general and interrelated questions seem to underlie most studies. The first question posed by researchers points to the situation-defining properties of variables. It asks what personal and situational factors encourage people to define a situation as one in which help is needed or absolutely required (e.g., an emergency). The second question is behavioral and asks what factors facilitate or inhibit helping once a situation is defined as one in which help is needed or required.

Most variables studied by researchers are pertinent to answering both questions, which taken together constitute a unitary process of prosocial action. For example, the ambiguity of situational cues such as a victim's distress (Clark & Word, 1974), number of bystanders present (Latané & Darley, 1970), and degree of victim need (Ashton & Severy, 1976) has been shown to directly affect the definition of a situation as an emergency and to indirectly activate helping behavior.

Both questions also find their way into all of the popular models of helping behavior, including the decision-making models of Latané and Darley (1970) and Schwartz (1977), the cost model offered by J. A. Piliavin and Piliavin (1972), and Staub's (1978) Person × Situation interactive approach. In addition, these models introduce variables and concepts designed to explicate the intervening processes that stand at the interface between the two questions.

The two general concepts of responsibility and cost predominate as the main explanatory tools in these models. Both concepts have multiple dimensions of meaning and have been employed in very different ways by researchers.

Responsibility has been given three distinct meanings in the helping literature. Theorists have described (a) the diffusion of respon-

This project was made possible in part by a Russell Sage Foundation residency fellowship in law and social science granted to the author. The author would especially like to thank Kristine Dwornik Bragg, who supervised the gathering of much of the data presented here.

sibility among multiple observers of an emergency (Latané & Darley, 1970), (b) personality differences in individuals' willingness to assume responsibility for the fate of others (Schwartz, 1970), and (c) the role of responsibility in social norms that prescribe that help be given to people in need (Berkowitz & Daniels, 1964; Walster & Piliavin, 1972). These separate usages of the concept of responsibility complement one another; each is appropriate for different research questions. It is clear, however, that some aspect of responsibility must be taken into account in describing any prosocial act. Responsibility is the sine qua non of helping. Every helping action requires the observer to role play and see the situation from the victim's perspective. In fact, the labeling of a particular action as helpful means not only that one person has made another's plight more pleasant or less painful but, by definition, that the first person has assumed responsibility for the fate of the second.

The concept of cost signifies a behavioral orientation. J. A. Piliavin and Piliavin (1972) presented a parsimonious cost model of helping behavior. This model consists of a 2 × 2 matrix of potential helping situations, with costs for helping matched against costs for not helping. Costs for helping that would typically discourage bystanders from intervening might be time, risk of physical injury, and being rebuked for not "minding one's own business." Costs for not helping can be divided into the risks of external sanctions, such as social ostracism, and the risks of internal sanctions, typically described as guilt or self-blame.

If one assumes that most of the cost factors relevant to a helping situation can be measured or reliably guessed, the Piliavin model makes straightforward predictions in two of the four cells. When costs for helping are low and costs for not helping are high, then a high rate of helping is expected. Conversely, when costs for helping are high and costs for not helping are low, then prosocial acts are naturally less frequent. However, predicting responses in the remaining two situational variations in the Piliavin model (high/high, low/low) is problematic.

The high/high situation is particularly interesting to researchers because it poses an interpersonal paradox, a "Catch-22," in which there is no satisfying way to resolve what is a classic case of avoidance—avoidance tension. J. A. Piliavin and Piliavin (1972) speculated that individual differences might be more influential under such circumstances, which could mean personality differences relevant to prosocial action (Schwartz, 1977), sex differences, or Person × Situation interactions such that individual characteristics may alter responses as a function of the relative strength of certain situation-defining variables (Staub, 1978).

This study began with the assumption that both responsibility and cost are necessary explanatory concepts in most helping situations. The research reported here was designed to test the effect of one situation-defining variable (degree of harm to a victim) and to explore possible sex differences under conditions that on one hand are conducive to helping (prior commitment obtained and person alone), yet pose the high/high cost dilemma on the other.

The type of helping behavior called for was intervention to stop a theft. Degree of harm to victim was manipulated by varying the value of the items stolen. Sex differences were studied by varying the sex of the bystander, thief, and victim. The experimental procedure first attempted to create pressures so that bystanders would have to make a considerable effort to deny personal responsibility for intervening. Subjects were alone so as to rule out diffusion of responsibility (Latané & Darley, 1970) and were engaged in casual activity (usually reading) so as to eliminate lack of helping due to competing commitments. In addition, each bystander subject was required to make a verbal commitment to watch the stolen items in the victim's absence. This setting of a clear obligation seems to create the high/high cost dilemma when coupled with the realities involved in stopping a thief. There are costs for not helping (incurring the victim's wrath, guilt for being complacent) and anticipated costs for helping (risk of physical injury, embarrassment, or incurring the wrath of a wrongfully

accused thief). I thus assumed the setting was ripe for investigating whether a clear situation-defining variable such as degree of harm, bystander/thief/victim sexual configuration, or both factors in combination would play a significant role in bystanders' attempts to resolve the high/high cost dilemma under conditions of high personal responsibility.

Predictions

1. I predicted a significant positive relationship between degree of harm to a victim and frequency of helping. I reasoned that greater harm would enhance the salience both of the bystander's personal responsibility and of the potential costs for not helping. The concept of degree of harm should not be confused with the similar but distinct concepts of need and dependency, which have both been shown to be correlated with helping (see Berkowitz & Daniels, 1963; J. A. Piliavin & Piliavin, 1972). Degree of harm concerns specific consequences for not helping, whereas need seems to address the probability of negative consequences if help is not forthcoming, and dependency concerns the degree of responsibility for intervening resulting from an existing relationship between victim and bystander. By my procedure I attempted to create the impression that negative consequences would certainly befall the victim while holding need and dependency constant.

The effect of degree of harm on helping under conditions of personal responsibility and high cost has not been studied previously. One study (Schwartz, 1970) varied degree of harm (or salience of consequences) in a study of willingness to donate bone marrow. Schwartz reported a curvilinear relationship between consequences and helping, but his manipulation of intensity of appeal to make a commitment and probability of the donor actually being called makes it difficult to compare his research with the present research.

2. This study was conceived as exploratory with respect to possible sex differences and Sex × Harm to Victim interactions. Although I was confident the high personal responsibility and high/high cost setting was best suited for discovering sex differences, the lack of a sound theory of sex differences in moral behavior and equivocal research findings precluded my stating a priori propositions (see Staub, 1978). Though researchers have reported some sex differences in prosocial behavior, the literature is far from consistent on the topic. Further difficulty stems from the usual problems in making between-studies comparisons of results in light of the different variables and operations used. In particular, researchers have not fully examined the potential effect of the sexual configuration of all of the participants. Numerous studies exist in which the sex of the bystander, the victim, or the wrongdoer has been studied individually, but only a few researchers have simultaneously varied the sex of more than one participant, creating a situation in which very little is known about the role of sexual configuration in helping. To my knowledge, prior to the research reported here, no one has orthogonally varied the sex of bystander, wrongdoer, and victim in a single study. Despite the lack of reliable empirical generalizations in this area I was hopeful that insights could be gleaned from previous studies and that these possibilities might combine with the operational setting employed in this research to shed new light on sex differences in prosocial action.

There is reason to expect sex differences in helping in the high/high cost situation created here. A previous study (Austin & McGinn, 1977) reported sex differences in reward allocation behavior and significant differences in verbal reports of motivations for allocation decisions. Specifically, under conditions of expectation of future interaction, males reported that their behavior was more influenced by cost avoidance considerations, whereas females rated friendship or interpersonal harmony factors as more important. There is some justification for extrapolating from reward allocation to helping, in that one could argue that both situations involve questions associated with treating another person fairly and what outcomes he or she will receive (see Walster & Piliavin, 1972). Accordingly, in the present research, females might be expected to show an overall higher rate of helping because of a greater sensitivity

to interpersonal harmony vis-à-vis the victim (i.e., costs for not helping). If this assumption is correct, then females might be willing to risk instigating conflict with a presumed thief because of a concern with harmony, whereas males might be more willing to risk harmony to avoid costs involved with intervention.

Some support for this conjecture can be found in helping studies. Most encouraging are studies that purport to show greater helping by females because of their heightened affective sensitivity, including empathy (Kilham & Mann, 1974) and guilt (Wallington, 1973). These findings are backed by Schwartz and Clausen's (1970) finding that females were more likely to intervene in an epileptic seizure when they were alone and by Bleda, Bleda, Byrne, and White (1976), who reported that females alone were more likely to report cheating when an identifiable victim was hurt by the dishonesty. Unfortunately, these studies shed little light on the role of sexual configuration. For example, Austin and McGinn (1977) studied only same-sex relationships, and Bleda et al. varied sex of bystander and wrongdoer, but not sex of victim. In addition to this qualification, many other studies have shown either no sex differences or greater helping by males. Latané and Darley (1970), Moriarity (1975), and Shaffer, Rogel, and Hendrick (1975) reported no sex differences in the willingness of bystanders to intervene in a theft. I. M. Piliavin, Rodin, and Piliavin (1969) reported that females were less likely to aid a person who collapsed in subway in a group setting,[1] and Gelfand, Hartmann, Walder, and Page (1973) found males more likely to report shoplifting behavior. However, once again, these studies did not fully study the sexual configuration, and the operational settings varied considerably. For example, Moriarity manipulated sex of thief, but victim/thief configuration was always cross-sex and sex of bystander was not taken into account; Shaffer et al. manipulated sex of victim and thief together, but the configuration was always cross-sex for all participants.

On the basis of previous research, predicting a Sexual Configuration × Degree of Harm interaction is also problematic. My initial thought that females would be victim oriented might suggest a high rate of helping regardless of degree of harm and might suggest that a majority of males would help only under substantial harm to the victim (because high harm might imply higher costs for not helping). These propositions are consistent with the speculations of Gelfand et al. (1973) that females are less inclined to report shoplifting because the victim is an impersonal business establishment, which thus does not activate their heightened affective sensitivity. Similar findings have been reported by Bleda et al. (1976), who found higher prosocial action by females only when there was an identifiable victim, and by Schopler and Bateson (1965), who explained a somewhat higher rate of female helping in terms of an apparent greater concern by males with their own outcomes.

This tentative prediction of greater overall helping by females, which should be most apparent when the degree of harm to a victim is modest, must again be held in abeyance because the supporting research did not examine sexual configurations.

Prior to conducting a field experiment that fully examined the effect of degree of harm and sexual configuration among participants, one pretest and two pilot studies were conducted. The results of these preliminary data-gathering efforts are briefly described below. All studies used identical procedures. Only the experimental designs differed.

General Procedure for All Studies

All subjects were college students at a large southern university. Subjects in the pretest, Pilot 1, and the field experiment attended the

[1] I. M. Piliavin et al. (1969) explained their results in terms of fewer costs for females for not helping because of their *role*. These researchers conjectured that the female role prescribes less initiative in emergencies and absolves women of the worst of public censure for not helping. This explanation is interesting in that it demonstrates the close relationship between the concepts of cost and responsibility in helping situations: Not helping is less costly to females because they are not responsible; they are not responsible because of their role (see Hamilton, 1978, on the importance of role in attributions of responsibility). Unfortunately, the data reported subsequently are exactly opposite to these conjectures.

same university; subjects in Pilot 2 attended a different university in the same state.

Subjects were located by selecting college students who were relaxing (usually reading) and seated by themselves in a corridor of a large university classroom building. One experimenter served as the potential victim and approached the bystander subject. He or she first gained a personal commitment from the bystander to watch his or her personal belongings. The experimenter paused directly in front of the bystander and asked, "Do you mind watching my things? I'll be back in a couple of minutes." All subjects consented in all studies. The experimenter then set several items next to and slightly forward of the bystander. This made it almost impossible for the subject not to notice what the items were and the theft that was about to take place.

The first experimenter (i.e., the victim) then moved off to a distant location to record the subject's response to the forthcoming crime. (Only a few subjects watched the first experimenter leave.) A second experimenter, who served as the thief, then casually approached the bystander and paused to examine the articles placed next to him or her. The thief passed directly in front of the subject and stopped for approximately 10 sec (as if to convey indecision as to his or her impending deed) before picking up the item. The theft was designed to be conspicuous.

The dependent variable was percentage of subjects in each condition who intervened to stop the theft. After intervening, or failing to intervene, subjects were told they had just been in an experiment. All subjects were unaware that this was the case. Subjects were then orally administered an open-ended questionnaire. The questions differed slightly for subjects who helped and those who failed to help. The questions assessed whether subjects noticed the theft, when they first knew a theft was going to occur, their first reaction to it, why they did not stop the thief, why the commitment to safeguard the item was not honored, and how they felt about the experimenter. The purpose of the study was then explained to subjects, and permission to use their data was obtained.

Pretest: Effect of Prior Commitment

In planning this research I first looked at the findings reported by Moriarity (1975) and Shaffer et al. (1975) on the importance of prior commitment for bystanders who observe a theft. Using different settings (public beach, Laundromat, or library) but stolen items of comparable value (portable radio or watch), Moriarity reported an intervention rate of 90%–100% for committed bystanders and 0%–20% for the uncommitted; Shaffer et al. reported a comparable 70% and 10% for the committed and uncommitted, respectively.

These polarized rates of intervention as a function of commitment impressed me so much that I first attempted to confirm whether they were a reliable baseline for reactions to a theft. Because I hold a rather humanistic view of people I wanted to take another look at the reactions of the uncommitted bystanders to see if they were really so passive in the face of a crime. By using the procedure described above, 20 bystander subjects (10 male, 10 female) were located and exposed to the theft of an electronic calculator—an item of considerable value (high harm to victim) and comparable with the items stolen in the Moriarity (1975) and Shaffer et al. (1975) studies. No prior commitment was obtained from these subjects. The victim was always female and the thief male. The victim stopped directly in front of the bystander and set a folder full of papers and a calculator down next to the bystander and then left, glancing back at her belongings. The results were dramatic. Not a single uncommitted bystander intervened to stop the theft. I interpreted this pretest data as corroborating previous research. Commitment appears to be a necessary condition for prosocial action in responses to the type of theft situation created here. Commitment, however, may not be necessary in all theft situations.

Pilot Study 1

This study was conducted as a group project for an undergraduate course. It allowed me to perfect the experimental procedure and provided a means for comparing the average

rate of helping of the subject population with data gathered in other theft studies. The item stolen was a calculator. The thief was always male (M) and the victim female (F). The sex of the bystander was varied (32 males, 36 females), making the bystander/thief/victim configuration M/M/F for half the subjects and F/M/F for the other half. Size of the thief was also varied. One half of the bystanders witnessed an extremely large male, and half viewed an average-sized male. This variable was designed to manipulate cost for helping.

I expected a Sex of Bystander × Size of Thief interaction in a 2 × 2 design. I assumed that risk of a physical confrontation was greater for males accusing other males of stealing. Thus, I reasoned fewer males would help when the thief was huge. My predictions were not supported. In a chi-square analysis no significant effects were found.[2] The rate of intervention was extremely high, ranging from 64.7% to 70.6%, and was fairly uniform. Females showed a slightly higher rate of helping, but it did not approach significance.

These null results suggested several empirical possibilities. First, when an initial commitment to help exists and the harm to the victim is substantial, then bystanders focus on costs for not helping, ignore the risk of physical danger for helping (e.g., size of thief), and show a high rate of helping. Perhaps if the risks of physical danger were more apparent, such as the presence of a gun, one could expect different results. However, the similarity of the rate of helping found here to the rates found in other theft studies (Latané & Darley, 1970; Moriarity, 1975; Shaffer et al., 1975) suggests that the present findings are reliable, though constrained within the limits of the apparent degree of physical danger that was apparent to the bystanders. Second, no sex differences were apparent.

Pilot Study 2

This study broke further ground for the field experiment. In a 3 × 2 design I examined the effect of harm to victim and sex of thief on helping. Degree of harm was operationalized by the value of the items stolen. The bogus victim placed books and folders (low harm), books, folders, and several record albums (moderate harm), or books, folders, and an electronic calculator (high harm) near the bystander. I predicted a significant main effect for harm, reasoning that commitment by itself may not be sufficient to produce the high rate of helping found in Pilot 1. Perhaps substantial harm to the victim is also necessary to activate the bystander's sense of personal responsibility (Schwartz, 1977) because of the potentially high costs for not helping. If this interpolation is correct, then low harm to the victim should beget a low rate of helping and high harm should elicit a high rate of helping.

This study was exploratory with respect to sex differences. I speculated that it would be more costly for a male to intervene with another male because of the physical confrontation, which I assumed would imply a competitive definition of the situation between males, but would be neutralized, or at least attenuated, in a cross-sex confrontation. If this assumption is correct, then one should observe males helping less when the thief is male and harm to victim is low. In this pilot I varied sex of thief, but used male bystanders only ($N = 72$). Once again the victim was always female, which produced M/M/F and M/F/F sexual configurations of bystander/thief/victim, though it was obvious that the results could only be analyzed in terms of sex of thief.

As Table 1 shows, the pilot data confirmed my prediction for the effect of degree of harm. As was the case in Pilot 1, male bystanders showed a high rate of helping (83.3%) when harm was high, but few bystanders helped when harm to victim was low (16.7%) or moderate (29.2%). This difference is reflected

[2] The frequency data for all studies were analyzed with a computer program (*Everyman's Contingency Table Analysis*, Note 1) that implements the log-linear methods for analyzing dichotomous data pioneered by Goodman (1972). It partitions explained variance in a manner similar to a squared multiple correlation regression analysis and yields analogues of main and interaction effects in the analysis of variance. I thank Thomas Guterbock for his assistance in making this program available.

Table 1
Effect of Degree of Harm to Victim and Sex of Thief on Male Bystanders' Helping Responses (Pilot 2)

Sex of thief	Degree of harm			Total
	Low	Moderate	High	
Male	2/12[a]	3/12	10/12	15/36
%	16.7	25.0	83.3	41.7
Female	2/12	4/12	10/12	16/36
%	16.7	33.3	83.3	44.4
Total	4/24	7/24	20/24	
%	16.7	29.2	83.3	

[a] The numerator denotes the number of bystanders who intervened; the denominator denotes the total number of bystanders.

in a significant main effect for harm, $\chi^2(2) = 26.19$, $p < .001$, although it is clear from Table 1 that substantial helping occurred only in high harm to victim conditions.

The overall finding of Pilot 2 is consistent with my reasoning that commitment to help by itself is not sufficient to activate prosocial action. In this case degree of harm was an important situation-defining factor. One could argue that substantial harm caused an increase in bystanders' sense of personal responsibility and their perception of costs for not helping.

Pilot 2 also found no sex differences. My speculation as to qualitative differences in same-sex and cross-sex confrontations was disconfirmed. This finding, when paired with Pilot 1 results, was discouraging as to the possibility of sex differences, given that the high/high cost situation combined with manipulation of harm to victim seemed to be well suited for discovering such differences if they indeed existed (e.g., J. A. Piliavin & Piliavin, 1972).

Field Experiment

Pilot 1 manipulated sex of bystander and found no significant effect. Pilot 2 found male bystanders to be unaffected by the sex of thief by itself or in combination with degree of harm to the victim. These results were perplexing. I thought I had created ideal conditions for the expression of sex differences. Subjects were alone; they were personally committed to assuming responsibility; they faced a personal paradox of high costs both for helping and for not helping; and they were exposed to different strengths of a potent situation-defining variable, which should have affected the intensity of personal responsibility they experienced and tipped the high/high cost balance in different directions.

It is clear, however, that the pilot studies were at best superficial tests of the role of sex in helping. Drawing on Austin and McGinn (1977), who suggested that males and females hold different motivational orientations toward others when they are responsible for another person's outcome, I designed a final field experiment, which provided a truer social psychological test for sex differences by manipulating the total sexual configurations among participants and degree of harm to victim.

I assumed females would be more victim oriented and concerned with interpersonal harmony under conditions of personal commitment and high/high cost. I reasoned that this possible "nomothetic predisposition" might translate into a higher rate of helping when harm to the victim was low. Pilot 2 showed that for males commitment by itself was not enough to produce help. Costs for intervening apparently outweighed costs for not helping when harm to the victim was low; males were willing to sacrifice the victim's belongings when their value was not high even when a commitment had been made. Females may not be so inclined. If they are indeed more victim oriented, then one should expect at least a moderate amount of help in the low-harm conditions.

Method

All eight possible bystander/thief/victim sexual configurations were employed along with low (folders and books) and high (folders and calculator) degree of harm conditions. The experimental design can be alternatively described as an 8×2 design (if sexual configuration is considered a unitary variable) or a $2 \times 2 \times 2 \times 2$ one (if the effect of sex of each participant is analyzed separately). Subjects were 352 male and female college students ($n = 22$ per cell). This design is capable of yielding a complete estimate not only of differences in bystanders' helping responses as a function of the

strength of a situation variable (i.e., harm) but also of separate effects for the role of sex of victim and thief.

Results

Table 2 shows that my tentatively held proposition that female bystanders would show greater overall helping and that this would be most apparent in low harm to victim conditions is correct. This observation is confirmed by log-linear regression analyses that uncovered a number of significant effects.

First, a significant main effect for degree of harm to victim, $\chi^2(1) = 31.13$, $p < .001$, reproduces the finding of Pilot 2 on the important situation-defining function of this variable. Table 2 shows greater helping in all of the high-harm conditions within each sexual configuration. In overall terms, 45.5% of bystanders intervened when harm was low and 75.6% when harm was high. Second, analyzing the helping data as a 2×8 design produces a highly significant main effect for sexual configuration, $\chi^2(7) = 32.85$, $p < .001$. However, this result only means that *some* aspect of the total sexual configuration among participants made a difference. Looking at the separate effects due to the sex of the individual participants in a $2 \times 2 \times 2 \times 2$ partitioning of the design produced a significant main effect for sex of bystander, $\chi^2(1) = 26.86$, $p < .001$, a marginally significant main effect for sex of the victim, $\chi^2(1) = 3.63$, $p < .07$, and a Sex of Bystander $\times$ Victim interaction, $\chi^2(2) = 30.90$, $p < .001$. Sex of thief had no effect on helping, $\chi^2(1) = .16$, *ns*. These findings are easily summarized by percentages. Collapsing across harm, 73.9% of female bystanders intervened, whereas only 47.2% of males did so; 65.9% of the female victims received help, but only 55.1% of the male victims were as fortunate. The Sex of Bystander $\times$ Victim interaction reflects the especially high number of females helped by other females: 80.7% of female bystanders helped female victims, and 51.1% of male bystanders helped females; 67.0% of female bystanders helped males in need, and 43.2% of male bystanders helped another male.

The third and most important finding of the field experiment is the highly significant

Table 2
Effect of Sexual Configuration Among Participants and Degree of Harm to Victim on Helping (Field Experiment)

Sex of bystander/ thief/victim	Degree of harm		Total
	Low	High	
M/M/M	4	14	18/44
%	18.2	63.6	40.9
F/M/M	13	18	31/44
%	59.1	81.8	70.5
M/F/M	4	16	20/44
%	18.2	72.7	45.5
F/F/M	12	16	28/44
%	54.5	72.7	63.6
M/M/F	8	15	23/44
%	36.3	68.2	52.3
F/M/F	17	20	37/44
%	77.3	90.1	84.1
M/F/F	6	16	22/44
%	27.3	72.7	50.0
F/F/F	16	18	34/44
%	72.7	81.8	77.3
Total	80/176	133/176	
%	45.5	75.6	

Note. M = male; F = female; $n = 22$ per cell.

Harm to Victim $\times$ Sexual Configuration interaction, $\chi^2(8) = 68.24$, $p < .001$. I had tentatively proposed (based on one related study and a literature review) that female bystanders show a much higher rate of helping in low harm to victim conditions. This hypothesis was confirmed. I found, as I had in Pilot 2, that male bystanders helped relatively infrequently in the low-harm condition (25.0%) but substantially more often in the high-harm condition (69.3%). The most impressive finding was the substantial rate of helping by female bystanders in both low- (65.9%) and high-harm (81.8%) conditions. The rate of helping by females in low-harm conditions fell just short of the proportion of males helping in high-harm conditions. Breaking this overall interaction effect into component parts produced significant Sex of Bystander $\times$ Harm, $\chi^2(2) = 61.04$, $p < .001$, and Sex of Victim $\times$ Harm, $\chi^2(2) = 35.49$, $p < .001$, interactions. Based on the significant Sex of Bystander $\times$ Sex of Victim interaction (reported earlier as part of the sexual configuration main effect) and the absence of any significant effect due to sex of thief, the

model that best fits these data (and therefore the most important empirical finding of this study) is a Sex of Bystander × Sex of Victim × Harm interaction, $\chi^2(3) = 65.92$, $p < .001$.

Interview responses. The postexperimental interview was open ended in character. It attempted to ascertain how the situation was defined by all subjects, those who helped and those who did not, and which, if any, justifications were used by nonhelpers. A similar pattern of responses emerged in each of the three studies. Bystanders' responses in the field experiment are summarized here in full appreciation of the tenuous nature of post hoc interview data.

All bystanders noticed the theft. Among bystanders who intervened (e.g., 213, or 60.5%), 170, or 79.8%, indicated that they noticed the theft as soon as the subject picked up the stolen object; the remainder did so as the thief walked away. A substantial number of the bystanders who helped indicated some hesitancy to intervene (97, or 45.5%), most often saying they thought the thief might really be the true owner of the objects (39, or 40.2%). More helpers indicated they "were aware of the potentially negative consequences" of not helping (103, or 48.4%) than of helping (74, or 34.7%). Some bystanders said both types of costs were important to them (62, or 29.1%). The remainder did not believe they considered either type of risk (36, or 16.9%). Among female helpers (130), 82, or 63.1%, mentioned costs for not helping; 27, or 20.8%, mentioned costs for helping; and 44, or 33.8%, mentioned both. Among male helpers (83), 47, or 56.6%, mentioned costs for not helping; 21, or 25.3%, mentioned costs for helping; and 18, or 21.7%, mentioned both. Thus, costs for not helping seemed to dominate responses among helpers, though the costs of intervention could not be ignored. This pattern suggests that the high/high cost tension was tipped in favor of costs for not helping among helpers. This finding is demonstrated by the remarks of one bystander: "What a fool I'd look like if she came back and somebody had ripped off her stuff. I know if I was in her place I would have been really steamed. And I said I'd watch her things anyways." A number of helpers (23, or 10.8%) said they would not have intervened if the stolen object had been of lower value (e.g., harm to victim). Finally, only a few helpers (12, or 5.6%) indicated they would have intervened without a prior commitment to guard the stolen object.

Among bystanders who failed to intervene (139, or 39.5%), a very substantial number indicated they "thought about saying something to the thief" (97, or 69.8%). One of these bystanders remarked; "What a relief! It's only an experiment!" Although a majority of the inactive bystanders were thus aware that a theft was quite likely taking place, only a handful (14, or 10.1%) failed to provide a justification for their inaction. The three most common justifications voiced by subjects were that they thought the thief was a friend of the victim (38, or 30.4%), the thief was the true owner of the objects (45, or 36.0%), or the victim sent the thief to retrieve the items (43, or 34.4%). Ninety-three male bystanders did not help; 15, or 16.1%, mentioned costs for not helping; 37, or 39.8%, mentioned costs for helping; 9, or 8.6%, mentioned both; and 41, or 44.1%, said both types of risk were unimportant to them. Forty-six female bystanders failed to intervene; 15, or 32.6%, mentioned costs for not helping; 12, or 26.1%, mentioned costs for helping; 2, or 4.4%, mentioned both; and 19, or 41.3%, indicated neither type of risk was a significant factor. Several patterns are clear from responses to these questions. First, both types of costs were seldom mentioned together, which was not the case with those who helped. Second, male nonhelpers indicated costs for helping were most important, and female nonhelpers mentioned costs for not helping slightly more often than males. Third, a substantial portion of nonhelpers of both sexes indicated risk was not a factor. This may be because of their awkward position of trying to justify a blameworthy action. Finally, a large number of bystanders (81, or 58.3%) said they would have intervened if the stolen items had been of higher value, which again probably reflects a need to justify blameworthy action. It should be kept in

mind that these patterns pertain only to the type of situation created in these studies.

Discussion

This research sheds some light on sex differences in bystanders' responses to a theft and on how sex interacts with situational variables. Researchers may find the postulated different motivational sets of males and females to be a plausible interpretation of these data. Since the experimenters were aware of the experimental conditions, there is a danger of experimental bias. However, the rates of helping compare favorably with the findings of other theft studies that used items of similar value under conditions of personal commitment (Moriarity, 1975; Shaffer et al., 1975). This comparability seems to argue against experimenter bias. The data reported here in combination with these previous theft studies also appear to provide an ecologically robust estimate of the rate of intervention to be expected in a theft under conditions of personal commitment, when the item is of reasonable value but the situation does not appear life threatening (e.g., when the types of potential costs involved are probably psychological rather than physical in nature).

Summary of Findings

1. When harm to the victim was substantial (theft of calculator), bystanders of both sexes showed an extremely high frequency of intervention (Pilot 1 and field experiment). This finding may be due to an increase in the salience of costs of not helping in the high-harm situation.

2. Degree of harm to victim by itself produced a significant increase in intervention to stop a theft (Pilot 2 and field experiment). This effect adds further credence to the interpretation that high harm added to personal commitment produces an increase in personal responsibility (because of the salience of costs for not helping) that is sufficient to guarantee a high intervention rate.

3. The most important result was the sex differences found when the total sexual configuration among participants was taken into account. The significant overall Harm × Sexual Configuration interaction demonstrates the utility of the interactionist approach to prosocial action recommended by Staub (1978) and Schwartz (1977). Sexual configurations exerted differential effects as a function of the strength of the situation-defining variable of degree of harm. I found that sex of thief made no difference in bystanders' behavior, but sex of bystander and sex of victim were influential by themselves, in combination with each other, and in combination with harm to victim. The Sex of Bystander × Harm interaction constitutes the most parsimonious fit to these data and accounts for a very large portion of the explained variance, $\chi^2(2) = 61.04$, $p < .001$, where the overall test produced $\chi^2(15) = 74.95$, $p < .001$, and the test for an overall Harm × Sexual Configuration produced $\chi^2(8) = 68.24$, $p < .001$. However, the theoretical significance of the greater helping elicited by female victims, alone and in combination with other variables, leads me to conclude that the three-way interaction between sex of bystander, sex of victim, and harm to victim, $\chi^2(3) = 65.92$, $p < .001$, best summarizes the empirical findings of this research.

The Effects of Systematic Variations in Information on Judges' Descriptions of Personality

Daniel S. Weiss

Institute of Personality Assessment and Research
University of California, Berkeley

The use of observers in personality assessment has recently been subjected to intensive scrutiny and criticism by several different commentators on the field. These criticisms have called into question some of the fundamental assumptions of personality assessment, and the evidence presented has been used to dismiss the findings that result from the use of human observers. The present study presents results demonstrating that observers can and do provide personality descriptions that reliably reflect variations in available information. Six different sets of information about 82 persons were furnished to a panel of 52 judges whose descriptions were then based on only one of the six information sets. The results of a series of analyses suggested that agreement among judges is not related to the amount of information used to formulate descriptions. Nonetheless, judges' descriptions did show a relationship between information and variation of specific descriptors, in that variation decreases in conditions where information is minimal. Finally, it was found that interperson similarity of description was associated with information, decreasing when judgments were based on personal contact and/or interviews and increasing when based only on stereotypic data.

Strong warnings about the continued use of observers in personality assessment have recently been sounded (e.g., Berman & Kenny, 1976; Bourne, 1977; Chapman & Chapman, 1967, 1969; D'Andrade, 1965, 1974; Fiske, 1971, 1973, 1974, 1976; Mischel, 1968, 1973; Shweder, 1975, 1977). The essential criticism has been that in making personality assessments, the observer is not sensitive to stimuli or, if sensitive, is unable to respond in ways that demonstrate such sensitivity. Further, critics claim that judges are unable to attend to or to report validly the actual relationships among the behaviors on which descriptions are based. Instead, implicit personality theory and linguistic accounts of personality are offered to explain the responses of personality assessors. If these criticisms are accepted, personality assessment methodology and the host of empirical findings dependent on these methods are suspect.

The most frequently cited evidence that observers' descriptions are invalid is the set of studies showing that despite differences in information about ratees, observers' trait ratings produce extremely similar factor structures of trait terms. Frequently referenced is the study by Passini and Norman (1966), in which undergraduate subjects were asked to rate each other on a set of traits previously selected and factorially grouped by Norman (1963). The members of this group of undergraduate students had had no previous contact or acquaintance with each other but did have several minutes together before the rating task began. During this period facts about

This study is based on a dissertation submitted in partial fulfillment of the requirements for the PhD degree at the University of California, Berkeley. The author acknowledges and appreciates the helpful suggestions and comments of Gerald Mendelsohn and Jack Block.

demeanor, dress, and bearing could be observed. Ratings were factor analyzed, and the resultant factor structure was compared to Norman's factor structure based on ratings where raters were more familiar with the persons being rated. The two factor structures were similar, leading Passini and Norman to conclude that *these* data were more a function of the rater than of the ratee. That is, judges in this study, who could not have known the characteristics of their targets, apparently used as a base their own implicit personality theories when they described their targets.

Using this basic approach, other researchers have shown similarity of factor structures across information conditions and have likewise concluded that personality ratings are invalid (e.g., Shweder, 1975). These conclusions, however, have been based on analyses of the relationships among stimuli, rather than on the ratings themselves. With respect to the wide citation and uncritical acceptance of the Passini and Norman study, a second paper that substantially moderates the Passini and Norman conclusions does exist and should be acknowledged. A curious aspect of this part of the controversy, however, is that this second relevant article, in the same journal, published during the same year and coauthored by one of the two authors of the Passini and Norman paper, is less frequently noted. This article (Norman & Goldberg, 1966) requires that the conclusions of the Passini and Norman study be severely delimited.

In this follow-up article, Norman and Goldberg further analyzed the Passini and Norman data and other data and found impressive evidence that the level of interrater agreement was a function of the degree of acquaintance. This finding was important because Norman and Goldberg recognized that the level of interrater agreement is relevant to the claim that implicit personality theories were the basis for the raters' descriptions. If the variance of ratings across ratees is in excess of that expected by chance, then this evidence can be taken to "imply that the raters are to some degree responding in like fashion to *some characteristics* of the ratees" (p. 684). When the reliabilities of both the composite and component ratings were calculated for Monte Carlo data, the original Passini and Norman data, a Peace Corps sample, and a fraternity senior sample, a correspondence was obtained between amount of reliability and amount of previous intimacy and knowledge of ratees. Noting that these findings provided necessary but not sufficient evidence for the validity of the rating data, Norman and Goldberg then demonstrated that with other convergent validational information (self-ratings and predicted peer ratings) in the Peace Corps and Passini and Norman sample, the validity diagonals of the Campbell and Fiske multitrait multimethod matrix yielded coefficients that lent "support not simply [to] the inference of differential ratee relevance in the data from the two groups, but also differences in the pertinence these data have to the personality characteristics of the ratees in the two cases" (p. 690). Given these data, the mere finding of similarity of factor structures of trait rating terms across samples of differing acquaintance cannot be taken as evidence of the insensitivity of the ratings to the ratees.

Wiggins and Blackburn (1976) presented data quite similar to that of Norman and Goldberg's. As part of their investigation of implicit personality theories, they too found that the factor structure of the traits was not different as a function of knowledge of the target being rated (in this case, stranger vs. friends). It was also shown that individual differences existed in the use of implicit personality theories, but the data did not allow the correlates of such differences to be clearly specified.

Despite the findings of similarity of factor structures, there are studies suggesting that the effects of implicit personality theories are not overwhelming. Block (1971), for example, has shown that a panel of judges' descriptions of a set of targets are more similar to each other within targets across judges than they are similar to descriptions across targets within judges. That is, Judges A, B, and C agree more about Target X than Judge A, B, or C agrees with himself or herself about targets X, Y, and Z. Nonetheless, there are many reasons why some research has found some personality judgments wanting.

A fundamentally important variable in per-

sonality rating studies is the amount and kind of information that judges have available. Thus, when comparing several different research studies, commentators have often lumped together types of judgment tasks that differ in the amount of information provided to the judges. Generalizations about the sensitivity of observers are inappropriate if it can be shown that the amount of information available to judges affects their judgmental processes and responses. Thus, the conclusions about the competencies of observers may need modification in the light of the limits imposed on judges by restrictions in the amount and kind of information available to them. Most prior work has not directly examined the variations in judgment due to variation in the amount and kind of information provided to judges. Studies that have examined information as a variable have generally cast results in terms of the validities of the judgments, despite the fact that the variables serving as criteria were often little better than the variables serving as predictors (see e.g., Golden, 1964; Kostlan, 1954; Sines, 1959). On balance, these studies did suggest differences in the validity of the judgments as a function of the amount and kind of information on which a judge based his or her predictions. It may also be noted that the conclusions of these studies were not based on analyses of the structure of personality ratings.

A summary of the research reviewed up to this point suggests several strong and clear conclusions. First, the robustness of trait rating factor structures to changes in information seems beyond dispute, especially when the set of trait terms employed has been previously selected on factorially derived grounds. Second, the robustness of such factor structures provides only equivocal evidence for conclusions about (a) the process used to make ratings or (b) the validity of the ratings that eventually produce the factor structure. Third, the modifications of personality ratings produced by variations in information have generally gone uninvestigated. One may assume however, that if the data base contains very little information, as have the data bases used by some critics, then raters have very little on which to base their ratings other than implicit personality conceptions. Thus, conclusions about the sensitivity of raters are unwarranted when based only on data gathered under meager informational conditions. If, however, amount and kind of information are systematically varied, and the ratings themselves, rather than their structure, are examined, then researchers have the opportunity to evaluate unbiased and relevant evidence of the sensitivity of observers of personality. The present study was undertaken to provide such evidence: The amount and kind of information given to observers was systematically varied, and the effects of information variation on personality descriptions were evaluated.

Method

The data used in this research derived from two sources. The first category contained data in the archives of the Institute of Personality Assessment and Research (IPAR). These data were personality descriptions of assessees made by staff members during a series of 1-day assessments held at the Institute. The second category contained data collected explicitly for this study. The collection of these new data required the use of other archival materials housed at IPAR,[1] namely the biographical records and interview protocols that new judges used to formulate personality descriptions of the assessees.

Subjects

One of the assessment projects carried out at IPAR was a study of attitudes and behaviors in the domain of population psychology (see Gough, 1973, 1975, for representative findings). A heterogeneous group of 402 persons living in communities surrounding the San Francisco Bay area was studied. Of this group, 82 (41 couples) came to the Institute during eight different 1-day assessment programs in 1974, 1975, and 1976. This group represented about 15% of all those to whom invitations to participate were made. All but one couple were married. The mean age for the 41 males was 31.12 ($SD = 5.26$), and for the 41 females was 29.20 ($SD = 4.51$). Their educational level in years was 13.73 ($SD = 1.80$) and 13.49 ($SD = 1.75$) respectively. The Hollingshead social class of the husband was 3.15 ($SD = .99$), where 1 is upper class and 5 is lower class.

---

[1] The author wishes to thank the Institute's director, Harrison G. Gough, for graciously making these data available.

Procedure

During the assessment day, each assessee was interviewed by two different staff members. One interview focused on the assessee's life history; the other, on the assessee's personal values with questions directed toward, but not limited to, issues in the realm of family and larger life goal orientations. Additional assessment procedures included a leaderless group discussion, an improvisational role-playing procedure, a couple interaction procedure, luncheon, a cocktail hour, a sit-down dinner, and finally a modified form of the party game charades. All these additional procedures were observed by all staff members, among whom were the individuals who conducted the interviews.

After the assessments were concluded, personality descriptions of each assessee were completed by the staff. The data utilized in this study came from two response instruments, the Adjective Check List (ACL; Gough & Heilbrun, 1965) and the California Q-sort (Block, 1961). Descriptions of each assessee were made on the ACL and Q-sort by both interviewers and by two or three other staff members who had previously been assigned to record their understanding of that assessee. These descriptions formed the materials in the archival data set. Thus, for any assessee, there were ACLs and Q-sorts completed by (a) a life history interviewer (for 2 of the 82 assessees, these data were missing), (b) a values interviewer (for 5 of the 82 assessees, these data were missing), and (c) two (for 30 of the 82 assessees) or three (for 52 assessees) staff members who had not interviewed that assessee but who had observed him or her during the assessment day (noninterview staff). Neither the life history nor the values interviewer was blind to the rest of the assessment procedures. Each was free to, and presumably did, draw upon information gleaned from the other assessment procedures to compile his or her ACL and Q-sort portraits. On the other hand, the noninterview staff did not have access to either interview protocol.

To extend the range of variation of amount and kind of information further, a second phase of data collection was undertaken. In this phase, three additional conditions or sources of information for judges' descriptions were provided. For each of these three conditions, one male and one female judge completed ACL and Q-sort materials for each case.

The first variant of what will be called the "protocol" data set was a *life history protocol condition*. For each case, the written life history interview protocol was read in its entirety by each of the two judges assigned to that case. In addition, demographic data (to be described below) were also given to the judges. Independently of each other, both judges then completed the ACL and the Q-sort for the case.

The second condition of the interview protocol data set was a *values protocol condition*. The same procedure used for the life history protocols was followed for the values protocols. One values interview from a male assessee in 1974 and one from a female assessee in 1976 were missing, reducing the n for the analyses on the values protocols to 80. The interview protocols for both the life history and values conditions consisted of handwritten records of the subjects' responses to a standardized set of questions. The interviewer's records were as nearly verbatim as possible. The actual questions used may be found in Weiss (1978).

The final condition in the study will be referred to as the *stereotypic-demographic condition*. The information available to judges in this condition consisted of sex, number of children, age, education, race, occupation, place of birth, and type of community of origin (either rural, suburban, or urban). Information about religious preference, a standard stereotype variable, was not included because these data were not available for all cases. In this condition, then, judges had neither direct nor indirect personal contact with the assessees. Their responses can be based only on their conceptions of personality characteristics and differences associated with *classes* of individuals.

Judges

The persons who comprised the assessment staff in 1974, 1975, and 1976 were either senior PhD faculty, full-time research personnel, visiting scholars, or advanced graduate students in personality or clinical psychology. The logic of the design requires that judgments in the various conditions vary only as a function of information and not also in terms of the panels of judges contributing descriptions in those conditions. Thus, great effort was made to secure protocol and stereotype judges who were similar to the staff members in the assessments.

There were 45 assessment staff members whose ACL and Q-sort descriptions were used in the assessments. Of these 45 judges, 21 were still at Berkeley and available and willing to participate as judges in the new study. In addition to these 21 persons, 7 advanced graduate students who had not participated in the assessments were asked to serve in the new study. These 7 judges were comparable to the advanced graduate students who had participated in the earlier assessments. Thus there were 28 judges in all who did Q-sorts and ACLs in the protocol and stereotype portions of the study. A total of 52 judges was employed for the combined assessment, protocol, and stereotype portions of the study.

If no case had been missing, there would have been a total of 902 descriptions. Thus, 34 descriptions or 4% of the theoretically complete file of data were missing, a minute fraction. Contributions to the total of 868 descriptions made by any single judge ranged from a high of 59 cases (7%) to a low of 2 cases (.2%). No case was described more than once by any judge. The mean number of descriptions for the total pool of 52 judges was 16.7 ($SD = 12.9$), or approximately 2%. That is, on the average, each judge contributed about 2% of the judgments on which subsequent analyses were conducted. Thus,

any biasing effects of idiosyncratic judges should be minimal.

Analyses and Results

Three separate, but related, sets of analyses were performed, each evaluating a different facet of the effect of information on observers' descriptions of personality. If the kind of information made no difference to the judges, then the results found in any one condition should be essentially identical to those found in any other condition. That is, if the information condition is irrelevant, then the degree to which assessees are differentiated from each other should not vary from one condition to another. Likewise, the mean level and variation of interobserver agreement should not be related to the information condition. The analyses were designed to provide evidence contradicting the position that information condition does not affect personality descriptions. Further, they sought to show that the manner in which information does affect description can support the conclusion that judges are reliable and sensitive "transducers" of variations in information and that their personality assessments can faithfully reflect the characteristics of the information available to them.

Interobserver Agreement

Studies employing rating tasks or procedures should report estimates of the reliability of the ratings. Because the information available to judges varied in this study, one might expect the amount of interobserver agreement also to vary with condition, as Norman and Goldberg (1966) had found. Because judges provided descriptions of target persons on two descriptive devices, the opportunity to evaluate interobserver agreement using different response formats was present. Three interobserver indices of reliability were calculated.

The first index involved the Q-sort. For each pair of raters for every case, the correlation over the 100 Q items was obtained. For the protocol and stereotype conditions, this correlation indexed interobserver agreement. For the two interview conditions, where only one judge described each case, observer agreement was calculated between the two interviewers. For the noninterview condition, there were 10 male and 13 female assessees for whom only two judges contributed descriptions; the remaining cases were described by three judges. For the former cases the correlation between the pair of judges was used as the index of agreement; for the latter cases, the mean correlation of the three pairs of judges was employed (in this analysis, and every analysis reported henceforth, all calculations involving the averaging of correlation coefficients employed Fisher's r-to-z transformation).

The second index of agreement was calculated for the judges' responses on the ACL. A correlation coefficient across the 300 items comprising the ACL was computed for each pair or set of raters for each case in the same fashion as was employed for the Q-sort. The dichotomous response format of the ACL means that the coefficients produced are actually phi coefficients. This index was therefore termed the ACLPhi index.

The ACL does not require judges to make a judgment for every item; that is, judges are free to check as many or as few adjectives as they believe to be descriptive. Since there are strong individual differences in the number of adjectives a judge is likely to check, regardless of information condition, this format poses some problems, being based on a fourfold tally of a present versus absent dichotomy. To overcome this problem, a third index of observer agreement was defined. The ACL items can be scored for 24 scales, some of which are empirically derived dimensions (e.g., self-control) and others of which are rationally derived scales based on Murray's need-press system. In the scoring algorithm the total number of adjectives checked is used as a correction factor when the raw scale scores are converted to standard scores. The net effect of such a procedure is to remove the differences on the scale dimensions that are attributable only to the differences in the total number of items checked. Thus, a correlation between two judges over the 24 scale scores will not be unduly influenced by differences in the total number of items

Table 1
Analysis of Variance of Reliability Indices

Index and condition	*n*	*M*	*SD*	Range	*F*
Q-sort[a]					
Life history/values interviews	75	.41	.19	−.09–.66	—
Life history protocol	82	.38	.28	−.50–.76	—
Values protocol	80	.38	.27	−.42–.73	.41
Noninterview	82	.41	.21	.07–.73	—
Stereotypic-demographic	82	.39	.22	−.11–.70	—
ACLPhi[b]					
Life history/values interviews	75	.35	.20	−.27–.63	—
Life history protocol	82	.27	.17	−.06–.58	—
Values protocol	80	.24	.18	−.13–.55	4.87*
Noninterview	82	.31	.17	−.02–.64	—
Stereotypic-demographic	82	.26	.17	−.10–.59	—
ACLScale[c]					
Life history/values interviews	75	.58	.57	−.76–.94	—
Life history protocol	82	.53	.56	−.80–.97	—
Values protocol	80	.45	.48	−.70–.90	.74
Noninterview	82	.53	.48	−.49–.91	—
Stereotypic-demographic	82	.54	.46	−.53–.94	—

Note. Means are *z*-transformed values; values for range are raw correlations. All values are between *pairs* of judges. ACLScale = Adjective Check List Scale. ACLPhi = Adjective Check List Scale with phi coefficient.
[a] Correlations based on 100 items; index shows heterogeneity of variance. [b] Correlations based on 300 items. [c] Correlations based on 24 scales.
* p (4, 396) < .001.

checked. Descriptions of the target cases were converted to the 24 standard scale scores using the conversion formula appropriate for each sex. For those cases described by three noninterview judges, the average correlation was used as the index. This index was termed ACLScale.

The interobserver correlations provided the raw data for the first group of analyses. A one-way analysis of variance was performed to evaluate the differences in level of agreement across conditions, for each index. The results of these analyses are reported in Table 1.

Q-sort reliability results. The first finding of interest is that for the Q-sort, there are no significant differences in interobserver agreement as a function of information condition. This result is not in accord with the Norman and Goldberg (1966) study. In the present research, judges reported that they found some conditions of information to be distinctly more helpful than others. One therefore might expect to find the strength of agreement among the judges to be related to the kind of information provided. That this expectation was not confirmed can be attributed in part to the nature of the Q-sort and in part also to the nature of the stereotypic-demographic information. Further, one may well ask if the expected differences were in fact warranted. A more detailed examination of this question will be deferred until the discussion section.

Of note, however, is the finding that the accompanying tests for heterogeneity of variance were significant, indicating that differences in the spread of agreement across the different conditions did occur. Agreement in the assessment conditions was never lower than −.09, whereas for the protocol conditions agreement went as low as −.50. On the other hand, in the protocol conditions, coefficients as high as .76 were obtained. The highest value in the assessment condition was .66.

ACL reliability results. The one-way analysis of variance of the mean interobserver agreement for the ACLPhi index did yield a significant overall difference, although infor-

mation condition accounted for only 4% of the variance in reliability coefficients. The ordering of the mean levels of interobserver agreement for the ACLPhi coefficient was associated with the greater information in the assessment conditions. Nonetheless, the lack of strength of the results does not strongly demonstrate that information condition affects reliability of description.

The ACLScale index, like the Q-sort index, did not show significantly different means as a function of information condition. The mean level of agreement for the ACLScale index, however, is higher than that for the other two indices. This finding is not unexpected, since the standardization procedure reduced the effects of number checked.

Differential Usage of Descriptors by Conditions

The second set of analyses concerns the use of the individual items of the two instruments (Q-sort and ACL). For the Q-sort it will be shown that judges' descriptions of assessees are more differentiated at the item level when amount and variety of information increase. For the ACL, it will be shown that judges use more descriptors with more varied information.

Q items. This analysis concentrated on item variances within condition; that is, on the variance of assessees' scores on a particular item within a particular condition. The basic array of scores consisted of 600 variances; 100 items over six conditions.

The six standard deviations for each item were calculated using Re-Q'd [2] data. Then tests of homogeneity of variance across the six information conditions were conducted. The Bartlett-Box F test and Cochran's C method (Winer, 1971) were used. Twenty-one of the 100 items showed significant heterogeneity of variance ($p < .05$) according to both tests. Eighteen more items, making a total of 39, showed significant departures from homogeneity of variance on one or the other test.

It was expected that the two interview conditions would, on the average, show the greatest variance of item placement across the 82 assessees because these two conditions were the ones with the most abundant and varied information available to each judge; that is, when information is most varied, judges should be able to make the most differentiated responses and hence produce the largest variance. To evaluate this anticipation, an anlysis that examined the relationship between amount of variation and information condition was conducted. The data for this next analysis were derived from the 6×100 array of standard deviations. For Q Item 1, the six within-condition standard deviations were ranked from 1 (the smallest SD) to 6 (the largest SD). This ranking procedure was repeated for the remaining 99 items. Thus, each of the 100 items was assigned a profile of six ranks. In effect, each profile indicates the ordering of the six information conditions in terms of the degree of variation in judges' descriptions. An analysis of variance of ranks across the six information conditions (Winer, 1971) was performed and evaluated by the Friedman test for the significance of the difference of mean ranks. The results of this analysis are presented in Table 2.

According to the Friedman test, $\chi^2(5) = 84.35$, $p < .0001$. The information condition that shows the highest rank and thus the most differential usage of items is the life history interview condition; the values interview and life history protocol conditions follow. Also of note is that the stereotypic-demographic condition shows the smallest mean rank of any of the information conditions, a result fully in accord with the impoverished information in that condition.

For the sets of 21 and 39 items showing significance on both or one of the heterogeneity of variance tests, results were also significant, with $\chi^2(5) = 38.39$ and $\chi^2(5) = 71.89$, $p < .007$, respectively. Moreover, these two sets reveal an important point. The SD of the mean rank for the stereotypic-demographic condition is, for both the 21 and 39

[2] It will be recalled that the number of judges varied from one to three within information conditions. In those conditions where there was more than one judge, the data were Re-Q'd to standardize all Q-sort distributions. This was accomplished by summing across judges and recasting the array of 100 sums into the forced distribution of values used for an individual judge's sort.

Table 2
Means and Standard Deviations of Q-Item Variance Ranks

Condition	*M*	*SD*
All items (n = 100)		
Life history interview	4.40	1.48
Values interview	4.21	1.38
Life history protocol	3.65	1.65
Values protocol	3.32	1.66
Noninterview	3.12	1.71
Stereotypic-demographic	2.30	1.49
Items with both heterogeneity of variance tests significant (n = 21)		
Life history interview	5.00	1.30
Values interview	4.78	1.03
Life history protocol	3.57	1.43
Values protocol	2.71	1.71
Noninterview	3.33	1.71
Stereotypic-demographic	1.90	0.99
Items with one heterogeneity of variance test significant (n = 39)		
Life history interview	4.85	1.14
Values interview	4.89	1.21
Life history protocol	3.59	1.52
Values protocol	2.74	1.58
Noninterview	3.59	1.71
Stereotypic-demographic	1.74	0.91

item sets, the lowest *SD* of the six conditions. The next lowest *SD* is, in both cases, the *SD* of the mean rank for an interview condition. Thus, not only are these conditions extreme in terms of variation of item placements across assessees as a function of information condition (as evidenced by the highest and lowest means), but they are also more consistently extreme (as evidenced by the low *SD*s) than are the other conditions. This result does not necessarily follow from the other findings in the analysis and thus underscores the effect of information on the variation of item placement within condition.

Although it is evident that the assessees are most differentiated in the interview conditions and least differentiated in the stereotype condition, it remains to be shown that the type of items sorted with the most variation are items for which the particular condition provided relevant information. There are no statistical procedures for determining this fit; goodness of fit must be judged psychologically.

Tables 3 through 8 report the Q items that showed the greatest variance in each of the six information conditions. That is, Table 3 reports the items that showed their greatest variation in the life history interview condition, Table 4 reports those items that showed their greatest variation in the values interview condition, Table 5 reports on the life history protocol condition, Tables 6, 7, and 8 contain items from the values protocol, noninterview, and stereotypic-demographic conditions, respectively.

Several points of interest may be noted in Table 3. First, 27 of the 100 Q items revealed their greatest variation in the life history interview condition; this was the largest number observed for any condition. The item content appears to be appropriate for what may be obtained in a life history interview. Four clusters of items may be delineated in the set of 27. Several deal with behavioral style and tempo (Items 4, 17, 20, 26, 30, 31, 77). Four refer to matters of sexuality (Items 58, 73, 77, 80). Five refer to social and interpersonal relationships (Items 17, 48, 49, 54, 89). The final category contains 12 items that refer to temperament and character (Items 9, 30, 41, 60, 62, 68, 70, 75, 77, 86, 97, 99).

Table 4, containing items showing their largest variation in the values interview condition, has 22 entries. As anticipated, this is the second largest number. The item content overlaps somewhat with that found in the life history interview condition, but this similarity is not unexpected. Personal contact and the interview transaction were as much a part of the one condition as the other. Items in Table 4 can be classified into (a) the social and interpersonal sphere (Items 27, 35, 36, 37, 38, 61, 64, 92), (b) character structure (Items 14, 39, 40, 42, 45, 72, 74, 98), and (c) expressive behavior (Items 43, 92, 98). A fourth category, (d), distinct from those observed in the life history interview condition, is the expected set of items on personal values (Items 22, 84, 91).

Table 5 lists the 19 items showing their highest variation in the life history protocol condition. All items, with the exception of item

52, which refers to assertive behavior, can be accommodated in the categories postulated for the life history interview condition. An important difference is that in the present listing the expressive behavior category has no entries. This omission is reasonable, as judges in this condition did not see the interviewee.

Items with largest variance in the values protocol condition are presented in Table 6. As anticipated, items referring to personal values are included, more, in fact, than for the values interview condition. This may have occurred because in contrast to the values interview condition, where *both* personal observations *and* factual information about personal values were available to a judge, in the values protocol condition only the latter were used. Items referring to personal values were thus more salient for the protocol than for the interview. In addition to the seven items dealing directly with values (Items 3, 7, 51, 63, 66, 83, 90), there were also four items referring to temperament (Items 16, 44, 46, 76) and two referring to intellectual functioning (Items 8, 51).

The items showing their largest variation in the noninterview condition are listed in Table 7. With the exception of a single item dealing with impulse control (Item 25), the remaining items can be classified under the heading of modes of interaction. This finding too is appropriate; that is, in this condition judges saw the target persons in casual social interaction throughout the assessment day but did not obtain detailed facts in the realms of values, life history, or character. These judges should then make most differential use of items pertaining to social style and physical demeanor.

Table 8 presents the items that showed their largest variation in the stereotypic-

Table 3
Q-Sort Items Showing Greatest Variance in Life History Interview Condition

4.	Is a talkative individual.[a]
9.	Is uncomfortable with uncertainty and complexities.
2.	Tends to be self-defensive.[a]
7.	Behaves in a sympathetic or considerate manner.
0.	Has rapid personal tempo; behaves and acts quickly.[b]
3.	Extrapunitive; tends to transfer or project blame.
6.	Is productive; gets things done.
0.	Gives up and withdraws where possible in the face of frustration and adversity. (N.B. If placed high, implies *generally defeatist*; if placed low, implies *counteractive.*)
1.	Regards self as physically attractive.[a]
2.	Seems to be aware of the impression he makes on others.
1.	Is moralistic. (N.B. Regardless of the particular nature of the moral code.)
8.	Keeps people at a distance; avoids close interpersonal relationships.
9.	Is basically distrustful of people in general; questions their motivations.
4.	Emphasizes being with others; gregarious.[b]
8.	Enjoys sensuous experiences (including touch, taste, smell, physical contact).[a]
0.	Has insight into own motives and behavior.[a]
2.	Tends to be rebellious and nonconforming.
8.	Is basically anxious.[b]
0.	*Behaves* in an ethically consistent manner; is consistent with own personal standards.
3.	Tends to perceive many different contexts in sexual terms.[a]
5.	Has a clear-cut, internally consistent personality. (N.B. *Amount* of information available before sorting is not intended here.)
7.	Appears straightforward, forthright, candid in dealings with others.[a]
0.	Interested in members of the opposite sex. (N.B. At opposite end, item implies *absence* of such interest.)[a]
6.	Handles anxiety and conflicts by, in effect, refusing to recognize their presence; repressive or dissociative tendencies.[a]
9.	Compares self to others. Is alert to real or fancied differences between self and other people.
7.	Is emotionally bland; has flattened affect.
9.	Is self-dramatizing; histrionic.[a]

[a] Both heterogeneity of variance tests significant ($n = 10$). [b] One test significant ($n = 3$).

Table 4
Q-Sort Items Showing Greatest Variance in Values Interview Condition

2. Is a genuinely dependable and responsible person.[b]
14. *Genuinely* submissive; accepts domination comfortably.
22. Feels a lack of personal meaning in life.[a]
27. Shows condescending behavior in relations with others. (N.B. Extreme placement toward uncharacteristic end implies simply an *absence* of condescension, not necessarily equalitarianism or inferiority.)
35. Has warmth; has the capacity for close relationships; compassionate.
36. Is subtly negativistic; tends to undermine and obstruct or sabotage.
37. Is guileful and deceitful, manipulative, opportunistic.
38. Has hostility toward others. (N.B. Basic hostility is intended here; mode of expression is to be indicated by other items.)[b]
39. Thinks and associates ideas in unusual ways; has unconventional thought processes.
40. Is vulnerable to real or fancied threat, generally fearful.
42. Reluctant to commit self to any definite course of action; tends to delay or avoid action.
43. Is facially and/or gesturally expressive.[a]
45. Has a brittle ego-defense system; has a small reserve of integration; would be disorganized and maladaptive when under stress or trauma.[a]
61. Creates and exploits dependency in people (N.B. regardless of the techniques employed, e.g., punitiveness, overindulgence). (N.B. At other end of scale, item implies respecting and encouraging independence and individuality of others.)
64. Is socially perceptive of a wide range of interpersonal cues.
72. Concerned with own adequacy as a person, either at conscious or unconscious levels. (N.B. A clinical judgment is required here; Number 74 reflects subjective satisfaction with self.)[b]
74. Is subjectively unaware of self-concern; feels satisfied with self.[a]
78. Feels cheated and victimized by life; self-pitying.[b]
84. Is cheerful. (N.B. Extreme placement toward uncharacteristic end of continuum implies unhappiness or depression.)[b]
91. Is power oriented; values power in self or others.
92. Has social poise and presence; appears socially at ease.[b]
98. Is verbally fluent; can express ideas well.

[a] Both heterogeneity of variance tests significant ($n = 4$). [b] One test significant ($n = 6$).

Table 5
Q-Sort Showing Greatest Variance in Life History Protocol Condition

1. Is critical, skeptical, not easily impressed.
5. Behaves in a giving way toward others (N.B. regardless of the motivation involved).
10. Anxiety and tension find outlet in bodily symptoms. (N.B. If placed high, implies bodily dysfunction if placed low, implies absence of autonomic arousal.)[a]
11. Is protective of those close to him. (N.B. Placement of this item expresses behavior ranging from overprotection through appropriate nurturance to a laissez-faire, underprotective manner.)
24. Prides self on being "objective," rational.
29. Is turned to for advice and reassurance.
34. Overreactive to minor frustrations; irritable.[b]
47. Has a readiness to feel guilty (N.B. regardless of whether verbalized or not).
50. Is unpredictable and changeable in behavior and attitudes.
52. *Behaves* in an assertive fashion. (N.B. Item 14 reflects underlying submissiveness; this refers to overt behavior.)
53. Various needs tend toward relatively direct and uncontrolled expression; unable to delay gratification.
55. Is self-defeating.
59. Is concerned with own body and the adequacy of its physiological functioning.[a]
65. Characteristically pushes and tries to stretch limits; sees what he can get away with.
67. Is self-indulgent.[b]
79. Tends to ruminate and have persistent, preoccupying thoughts.[b]
82. Has fluctuating moods.
87. Interprets basically simple and clear-cut situations in complicated and particularizing ways.
94. Expresses hostile feelings directly.

[a] Both heterogeneity of variance tests significant ($n = 2$). [b] One test significant ($n = 3$).

Table 6
Q-Sort Items Showing Greatest Variance in Values Protocol Condition

7.	Has a wide range of interests. (N.B. Superficiality or depth of interest is irrelevant here.)
7.	Favors conservative values in a variety of areas.
8.	Appears to have a high degree of intellectual capacity (N.B. Whether actualized or not; originality is not necessarily assumed).
3.	Is thin-skinned; sensitive to anything that can be construed as criticism or an interpersonal slight.
6.	Is introspective and concerned with self as an object. (N.B. Introspectiveness *per se* does not imply insight.)
4.	Evaluates the motivations of others in interpreting situations. (N.B. Accuracy of evaluation is not assumed.) (N.B. Again, extreme placement in one direction implies preoccupation with motivational interpretation; at the other extreme, the item implies a psychological obtuseness; subject does not consider motivational factors.)
6.	Engages in personal fantasy and daydreams, fictional speculations.
1.	Genuinely values intellectual and cognitive matters. (N.B. Ability or achievement are not implied here.)
3.	Judges self and others in conventional terms of "popularity," "the correct thing to do," social pressures, and so forth.
6.	Enjoys aesthetic impressions; is aesthetically reactive.[a]
9.	Is sensitive to anything that can be construed as a demand. (N.B. No implication of the kind of subsequent response is intended here.)
6.	Tends to project his own feelings and motivations onto others.[b]
8.	Able to see to the heart of important problems.
0.	Is concerned with philosophical problems, e.g., religions, values, the meaning of life, and so forth.[a]

[a] Both heterogeneity of variance tests significant ($n = 2$). [b] One test significant ($n = 1$).

emographic information condition. Ideally, o item should have shown greatest variance n this condition. In fact, none showed signifiant heterogeneity of variance, and their anking highest in this condition may best e viewed as a minor fluctuation around the nore or less equivalent variances of the six onditions.

We may now summarize the Q item variance results. Overall, the pattern is a strong ne; the three assessment conditions, in which ssessees were actually observed, contain all he items making reference to physical qualties of appearance and bearing. This finding s hardly surprising, but its absence would ave raised serious doubts about the effects f information on personality descriptions. he noninterview condition, where no intiate contact occurred but persons were nonetheless personally observed, contained items elating to social interaction and social skills. he values protocol condition contained the bulk of the values items. The two life history nformation conditions (interview and protocol) contained a preponderance of items dealng with personality style, socialization, adjustment, and sexuality, all topics that were explicitly discussed in the interview. Finally, the stereotypic-demographic information condition contained only five items, all lacking significant heterogeneity of variance.

Viewing the six tables as a whole reveals

Table 7
Q-Sort Items Showing Greatest Variance in Noninterview Condition

15.	Is skilled in social techniques of imaginative play, and humor.[b]
18.	Initiates humor.[a]
19.	Seeks reassurance from others.
21.	Arouses nurturant feelings in others.
25.	Tends toward overcontrol of needs and impulses; binds tensions excessively; delays gratification unnecessarily.[b]
28.	Tends to arouse liking and acceptance in people.[b]
33.	Is calm, relaxed in manner.[b]
56.	Responds to humor.
57.	Is an interesting, arresting person.
81.	Is physically attractive; good-looking. (N.B. The cultural criterion is to be applied here.)[a]
88.	Is personally charming.[a]
93.	*Behaves* in a masculine style and manner *or Behaves* in a feminine style and manner. (N.B. The cultural or subcultural conception is to be applied as a criterion.)[b]
95.	Tends to proffer advice.

[a] Both heterogeneity of variance tests significant ($n = 3$). [b] One test significant ($n = 8$).

Table 8
Q-Sort Items Showing Greatest Variance in Stereotypic-Demographic Condition

6.	Is fastidious.
71.	Has high aspiration level for self.
85.	Emphasizes communication through action and nonverbal behavior.
96.	Values own independence and autonomy.
100.	Does not vary roles; relates to everyone in the same way.

another interesting and important result. As information decreases, so does the number of items that show significant heterogeneity of variance. So, for example, in Table 3, which tallies items for the life history interview condition, nearly half of the items show significant heterogeneity according to one or both tests. This contrasts with Table 8, which shows no significant items in the stereotypic-demographic condition. The number of significantly heterogeneous items is proportional to the total number of items in each condition, which is in turn related to the amount and kind of information available in each condition. This pattern, then, further corroborates the abilities of judges to respond to and reflect the variations in information on which their descriptions are based.

ACL items. To show that the effects of information are not confined to a single descriptive method, an analysis of the ACL data paralleling that for the Q-sort was performed. This analysis involved comparing across conditions the total number of adjectives checked about assessees. In the assessment conditions, where judges had direct contact with their targets, the mean number of adjectives checked per assessee should be higher than for the protocol and stereotype conditions, where contact with the target was only through written documents. The total number of adjectives checked for each case by each judge was computed. Differences between conditions were evaluated by a one-way analysis of variance. The results are presented in Table 9.

Table 9
Analysis of Variance of Total Adjective Check List Items Checked

Condition	*n*	*M*	*SD*	*F*
Life history interview	80	89.96	20.54	—
Values interview	78	85.20	18.91	—
Life history protocol	164	58.27	20.37	92.40*
Values protocol	160	54.96	22.04	—
Noninterview	224	83.93	19.67	—
Stereotypic-demographic	164	51.90	23.25	—

* p (5, 864) = .0001.

The findings for the ACL parallel those found with the Q-sort. The total number of adjectives checked about a target person varies substantially with information condition, which accounts for 34% of the variance. When judges had personal contact with their targets, they checked approximately 85 items as descriptive; judges without such contact checked only about 54 adjectives. Scheffé's test for differences among the means of the total number of adjectives checked reveals two homogeneous subsets significant at the .05 level. As predicted, the protocol and stereotype conditions form one group and the assessment conditions form the other. Thus on a second and independent measuring instrument, judges in this study demonstrated that information does indeed affect description: When information available to judges is more abundant and varied, their descriptions are correspondingly fuller and more detailed.

Within-Condition Homogeneity of Description

In the analysis just reported, differentiation among assessees was examined at the level of individual items. In the analysis to follow, differentiation among assessees will be examined at a more global level. Specifically, the Q correlations between assessees provide the basic data. For each sex separately, six matrices of interperson correlations were obtained, one in each condition. As Block (1961) notes, the Q correlation is a convenient index of interperson similarity. If information condition had no effect, then the mean level of similarity between assessees would be no greater in any one condition than in any other. If, however, information does affect description, then a relationship between condition and similarity should obtain. The

stereotypic-demographic condition should produce the most homogeneous (i.e., the least differentiated) set of descriptions, and the interview conditions the least homogeneous set. In Table 10 the mean interperson Q correlation is shown for each information condition.

The patterning of the means of interperson similarity emphasizes the results from the analysis of variance of ranks; the least differentiation among assessees was obtained in the stereotypic-demographic condition, where the mean of all correlations between male assessees was .40 and the corresponding mean for females was .44. In marked contrast, in the life history interview condition, the mean interperson correlation for males was .15 and for females was .14. Information condition accounts for 33% of the variance in correlational similarity. Additionally, the Bartlett-Box F test shows significant ($p < .01$) heterogeneity of variance. The life history interview condition shows less spread than the other conditions do. An interesting, albeit unanticipated, finding was that there was a significant difference in mean similarity between males and females in the stereotypic-demographic condition. The females were described more homogeneously than the males, $t(80) = 2.60$, $p = .01$.

In bold terms these analyses show that when little or no information is available, differentiation among assessees is low. On the other hand, when information is detailed, intimate, and characterologically revealing, judges describe their targets in a far more differentiated fashion. Finally, when the amount of information available is intermediate, the level of differentiation is intermediate. This is perhaps the clearest evidence that the degree to which judges can differentiate among assessees is a direct function of the degree to which differentiating information is available to them.

Table 10
Analysis of Variance of Interperson Similarity

Condition	n	M	SD	F
All assessees (df = 5, 479)				
Life history interview	80	.14	.09	—
Values interview	77	.19	.15	—
Life history protocol	82	.24	.13	49.20*
Values protocol	82	.28	.14	—
Noninterview	82	.29	.14	—
Stereotypic-demographic	82	.44	.13	—
Male assessees (df = 5, 235)				
Life history interview	40	.15	.08	—
Values interview	37	.16	.12	—
Life history protocol	41	.26	.13	24.59*

Discussion

The study reported above has been concerned with a basic and fundamental problem in personality psychology: Are human observers capable of giving reliable and sensitive descriptions of personality? Recent writing in personality assessment has questioned the continued use of raters of personality, claiming that the data they produce are biased, unreliable, and insensitive to the "actual behavior" of the ratee. The central assertion of the criticisms of personality ratings is that the ratings do not reflect the "actualities" of the stimuli upon which they are based. The processes by which observers make their judgments are hypothesized to reflect various kinds of artifacts (e.g., logical error, illusory correlation). This pessimistic conclusion has been based on several types of analyses, most of which have considered solely the patterning or intercorrelations of the ratings. The evidence from the ratings themselves, however, has not generally been evaluated. This step logically comes prior to examining the structure of the ratings, and if convincing evidence of the tenability of ratings can be demonstrated, then the results derived from analyses of the patterning of ratings become phenomena to be explained, rather than

demonstrations of the irrelevance of personality ratings.

To demonstrate the tenability of observers' ratings of personality in this study, the amount and kind of information provided to judges was systematically varied, and the effects on the subsequent ratings were examined. If judges' ratings were insensitive to the actualities of the information, then no systematic effects should have been produced by the systematic variation in information. If, however, variations in information produce clear, comprehensible, and predictable variations in personality descriptions, the inescapable conclusion is that judges can and do respond sensitively to the information from which descriptions are made.

We may now discuss the evidence in this study that supports an optimistic view of the capacities of observers. A primary demonstration of the effects of information on description examined the differential use of descriptions. The analysis of variance of ranks of Q item variances and the analysis of the mean number of total adjectives checked on the ACL both provided strong evidence that judges perceived, integrated, and responded to the information each condition provided.

An alternative explanation for the differential variation of Q item placements across conditions might be that adventitious aspects of the assignment of cases to judges within condition, rather than responsiveness to changes in information, produced the observed results. But this reasoning would not explain why items that showed differential variation were items with content that was relevant to the information condition in which they showed increased variation. This second aspect of the data argues strongly against such an alternative explanation. It argues for judges' competent use of information.

The ACL demonstrates the effects of information on description in a different fashion. Information in the protocol and stereotype conditions led judges to reduce markedly the sheer number of items judged to be descriptive of an assessee. Thus, without a forced format, as in the Q-sort, the judges' own descriptive behavior on the ACL demonstrates their responsiveness to variations in information. When the information available lacks immediacy, i.e., when the person is not physically present with the judge, descriptions are less full and rich.

The analysis of interperson similarity probably provided the most vivid and comprehensible demonstration of the effects on personality assessment of variations in information. If differentiation in personality assessment is a function of information, then the degree of homogeneity in description should be related to information condition. The analyses showed that the amount of similarity of description among persons was inversely related to the amount of information. Additionally, the homogeneity of variance of mean interperson correlation decreased in the condition where information was greatest—the life history interview condition. This finding, perhaps self-evident, is nonetheless heartening to those who have argued for the continued use of the human observer in personality assessment. Because the target sample was the same in each condition, because the measure used to describe the targets was the same in each condition, and because the amount of judge overlap was great, the findings are best interpreted as showing that judges altered their descriptive behavior depending on what information was provided.

The analysis of the level of interobserver agreement as a function of information condition yielded less straightforward results. Differences between conditions were not of large magnitude for the ACL and did not occur with the Q-sort; differences in the homogeneity of agreement coefficients were present, however. Several reasons may be suggested for finding equivalent levels of reliability with the Q-sort:

1. The Q-sort distribution is forced and therefore if a core of agreement exists, it will be magnified as a function of the equalization of means and standard deviations for all judges, regardless of the information they had.

2. The item content of the Q-sort is quite variable; some items are rarely sorted as strongly characteristic of anyone. That is, the location of placements for some items is highly modal, and agreement is therefore heightened relative to a set with more normally distributed items, whatever the condition of information.

3. For the stereotypic-demographic condition, in which agreement was as high as it was for the other conditions, it may very well be the case that judges possess a shared cultural stereotype and can, if need be, draw upon this for their descriptions when they have no alternative. Nonetheless, this shared stereotype does not provide the detailed information needed to make item placements for many of the Q items. Hence, the level of agreement reached is only moderate.

The meaning of the level of agreement that exists for the stereotypic-demographic condition is revealed by the analyses demonstrating that the agreement reached under impoverished information was reached at the price of differentiated descriptions of the targets. Thus judges who do not have personally relevant information agree with each other about the same target as much as life history interview judges do; further, across assessees they agree to a much larger degree. In fact, the stereotypic-demographic condition is the only condition in which there is not a single negative mean interperson correlation for any assessee. This is what one would expect if the judges did not have the requisite information to differentiate among assessees but nonetheless had knowledge about characteristics associated with classes of persons.

The crucial question in regard to interobserver agreement is whether equivalent levels across information conditions undercut conclusions about the sensitivity of observers. Agreement for all conditions was only moderate. Parenthetically, it should be noted that the reliabilities reported are analogous to interitem correlations. The reliabilities of the composite descriptions furnished by four or five judges for these 82 cases had a mean value of .702 and a median value of .729 on the Q-sort. These composite descriptions are routinely employed in assessment studies rather than the descriptions from pairs of judges. Nonetheless, it is still the case that the level of agreement is equivocal with respect to the sensitivity of observers. For example, what should be said about a 32-year-old housewife and mother of two, having 16 years of education and working part-time as a substitute teacher? Artifactual accounts of personality assessment based on implicit personality theory or semantic similarity of trait terms seem to require a much higher degree of consensus than that which in fact occurs. This suggests that shared assumptions about personality are not as pervasive as some commentators have indicated (Shweder, 1975, 1977).

An implication of the findings on agreement is that there may be both a floor and a ceiling, below or above which consensus cannot extend. Given less than total but more than minimal information about a large set of personality variables for which judgments will be requested, judges may well be able to agree to a certain point, regardless of the type of information with which they are furnished. For example, if it can be shown that in conditions of impoverished information, agreement among judges is principally a function of strong consensus about a small number of descriptors, whereas in conditions of more abundant information agreement stems from more mild consensus about a larger number of descriptors, our understanding of the nature of interjudge agreement would be deepened. Alternatively, it may be the case, as some of the clinical judgment studies show, that more information leads to the discounting of base-rate information that is actually more accurate and predictive. The role of extent of information is psychologically complex, as this second formulation makes clear.

In arguing for an acceptance of the data that observers provide about personality, we do not suggest that this method is the only appropriate method for study in personality. Nor do we suggest that the use of observers has reached its practical limits in regard to reliability and validity. Training, more familiarity with the response instruments, and a larger number of observers are all ways of increasing the reliability and accuracy of observers' judgments. It is, of course, obvious that the results discussed here do not certify that the ratings of these assessees are valid. That question must await further analyses of the data. But it is reasonable to assume that the prerequisites for validity are present, and that a clear possibility for impressive nonrating correlates exists for these data. A key consideration, moreover, in establishing accuracy is that for many, if not most or all,

studies using other methods of assessment, ultimately validity rests on the correspondence of observations with the criteria laid down by observers. As argued elsewhere (Block, Weiss, & Thorne, 1979), appeals to behavior counts are no less dependent on observers than are ratings. Disagreement among researchers arises regarding the meaning of the observations not their necessity.

The present report has asserted that the use of the human observer as a personality assessment tool is reasonable and useful and that personological descriptions furnished by observers are reliable and often acutely sensitive to the nature of the stimuli on which they are based. The conclusion is that observers are sensitive encoding "instruments." Despite the known biasing effects on ratings of halo and the logical error, for example, it is unlikely that there exists at present a method more economic, precise, and valid for gathering personality assessment data than that utilizing the human observer. The basic soundness of the data in this study supports this observation.

Announcing a new Quarterly Journal . . .

JOURNAL OF

Occupational Behaviour

Editors:

Cary L. Cooper
Department of Management Sciences, University of Manchester Institute of Science and Technology

James C. Taylor
Center for Quality of Working Life, University of California, Los Angeles

An international journal of social science research on human behaviour in the work place and on related social change. For all social, behavioural and industrial scientists, teachers and practitioners who are concerned with occupational behaviour and management

Typical areas of coverage in the *Journal of Occupational Behaviour* will be:

★ Innovations in job design and enrichment
★ Work experience, occupational satisfaction and stress
★ Industrial participation and democracy in the work place
★ Career development, retraining and retirement
★ Work in its legal and socio-economic context
★ Implications of Work for Leisure, the Family and Public Life

Subscription Details: Volume 1 (1980) Quarterly UK £22.50 Elsewhere US $55.00
Special Subscription Rate for Personal Subscribers: UK £12.50 Elsewhere US $30.00
(Air-speeded delivery to USA and Canada)
For a free specimen copy, or for further information, please write to the Subscription Department at the more convenient address below.

The Journal Supplement Abstract Service is an information service providing ready access to psychology-related materials not available through conventional communication channels.

JSAS Selects and Disseminates:

- Educational materials
- Massive data collections
- Methodological techniques and procedures
- Major projects in progress
- Descriptions of effective techniques or programs
- Technical reports
- Fresh looks at controversial issues
- Invited lectures
- Management of psychological resources
- APA task force reports
- Bibliographies
- Literature reviews

Manuscripts are accepted by a panel of editors. They meet the same high standards set for APA's journals, but are not bound by conventional restrictions of format, length, or editorial policy.

Available titles are listed in the quarterly JSAS *Catalog of Selected Documents in Psychology.* The catalog includes abstracts of newly accepted manuscripts along with manuscript length, price, and ordering information. Each issue of the catalog contains about 50 abstracts. Full-text manuscripts may be purchased individually in paper or microfiche.

Subscription rates for the quarterly catalog are $6 for APA members and $14 for nonmembers (foreign, $16). Please include full remittance for orders of $25 or less. To order, make check payable to American Psychological Association.

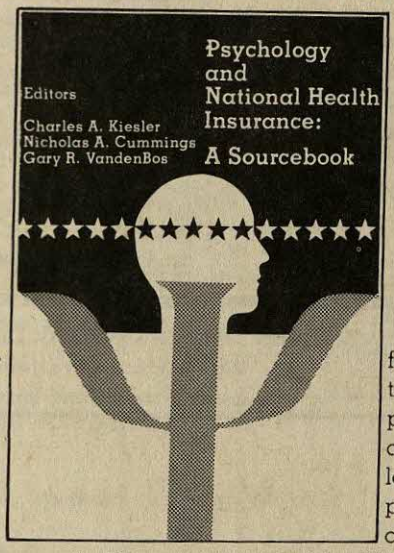
Psychology and National Health Insurance



Psychology and National Health Insurance: A Sourcebook is the only collection of current readings on the status and future of psychology in national health insurance programs. Emphasizing the valuable services offered by psychologists and examining professional standards, the editors provide legislators, psychologists, and the general public with a collection of articles reprinted from a variety of sources as well as new material.

Included are discussions of the following topics: • Surveys on the numbers, locations, and practices of health service providers in psychology • Evaluation; accountability, service review issues • Redistributive aspects of NHI • Current legal and legislative status of professional psychology • Issues in professional training • National health insurance plans • Psychotherapy outcomes and psychological interventions in physical health • Value of prevention services in national health insurance programs.

A detailed index and full citation of all materials are also provided.

Edited by **Charles A. Kiesler, Nicholas A. Cummings,** and **Gary R. VandenBos,** 1979, 680 pages, 7" x 10", index. Price: $19.50 hard cover, $15.00 soft cover.

To order, write to: American Psychological Association, Order Dept. • 1200 Seventeenth Street, N.W. • Washington, D.C. 20036.

Orders of $25 or less must be prepaid.

New Titles in Psychology from O,G & H

SKILL IN NONVERBAL COMMUNICATION

Individual Differences

Edited by

ROBERT ROSENTHAL,

Harvard University

There are increasing indications that interpersonal interactions may be affected in important ways by the interactants' ability to decode and to encode nonverbal cues. These papers offer major evidence for important research investigating the ways in which these skills in decoding and encoding nonverbal cues are related to personal characteristics and to the outcomes of social encounters. Their various findings support, or amplify, or challenge views held in the field of nonverbal communication — some speak to issues rarely raised before — all of them contribute to the understanding of nonverbal communication.

BASIC DIMENSIONS FOR A GENERAL PSYCHOLOGICAL THEORY

Implications for Personality, Social, Environmental, and Developmental Studies

ALBERT MEHRABIAN,

University of California, Los Angeles

This book proposes an approach to the study of human emotions based on a concise description of emotional states which uses a three-dimensional framework of temperament (pleasure, arousability, dominance) for describing emotional traits. This framework provides a set of independent factors for studying numerous problems in personality, social, developmental, and environmental psychology. The author examines the implications of this framework for understanding differential preferences for various situations, explores the ways in which emotional states can lead to seeking or avoiding different means of chemically modifying the bodily environment and concludes with a discussion of various theoretical and experimental studies based on these theories.

INNER PERSPECTIVES FROM DORSEY

Personality Theories: A Comparative Analysis, 4th Edition

Salvatore R. Maddi, University of Chicago

Thoroughly absorbing, this text compares and contrasts many theoretical viewpoints with a comprehensive, consistent, and original framework for the personality field. Pertinent issues are posed, and research studies are examined for their value in resolving the issues. Teacher's Manual.

Coming in 1980.

Understanding Social Psychology, Revised Edition

Stephen Worchel, University of Virginia, and Joel Cooper, Princeton University

The traditional areas of social psychology are covered in both theory and research along with demonstrations of how social psychology can and cannot be used to understand "real world" incidents. This edition includes a new chapter on socialization. Student Study Guide. Teacher's Manual.

Published 1979.

Personality: Strategies and Issues, 3rd Edition

Robert M. Liebert, State University of New York at Stony Brook, and Michael D. Spiegler, Providence College

This volume provides a widely resepcted and highly readable introduction to major strategies and issues in the psychological study of personality. Students can see clearly both strengths and weaknesses of each viewpoint. New discussions of attribution theory and cognitive behavior modifications are included. Instructor's Manual.

Published 1978.

The Journal of Personality and Social Psychology publishes original reports of research, methodology, theory, criticism, and literature review in the fields of personality and social psychology of normal processes and populations. Submitted manuscripts should delineate an important question and provide a clear answer to it. In the case of research reports, this will often require demonstration that the reported results are generalizable beyond a single research setting. Consult the editorial in the January 1976 issue (Vol. 33, pp. 1–7) for a detailed statement of policies and instructions to authors.

Manuscripts: Submit manuscripts in quadruplicate, prepared according to the *Publication Manual of the American Psychological Association* (2nd ed.). Copies should be highly legible and will not be returned to authors unless they are original typewritten copies. Mail manuscripts according to instructions on p. 1439 of the August issue.

Required supplementary information: Manuscripts cannot be reviewed for publication unless the author provides supplementary information in the following categories: (a) a cover letter that indicates the relation (or the lack of relation) of the submitted manuscript to other papers by the same author(s) that are currently submitted, in press, or recently published; (b) one copy of each such related paper; (c) one copy of a statement of the procedures of the research reported in the submitted manuscript in sufficient detail to serve as a guide for conduct of an exact replication; and (d) one copy of the summary tables (e.g., correlation tables, analysis of variance summaries) for the *major* analyses reported. If it appears that the supplementary materials in categories (c) or (d) might be bulky, the author should exercise judgment and restraint in selecting what to send. It is not necessary to send supplementary material that repeats verbatim manuscript content.

After a manuscript is accepted, authors will be expected to provide assurance that their data are available in unanalyzed form for reanalyses by other investigators and that their research procedures were consistent with the American Psychological Association's published principles of research ethics, except insofar as may be detailed otherwise in the manuscript.

Copyright and Permission: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permission is normally granted contingent upon like permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of $10 per page, table, or figure. Abstracting is permitted with credit to the source. Permissions and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use their own material commercially. Permission and fees are waived for the photocopying of isolated articles for nonprofit classroom or library reserve use by instructors and educational institutions. Libraries are permitted to photocopy beyond the limits of U.S. copyright law: (1) those post-1977 articles with a code at the bottom of the first page, provided the per-copy fee indicated in the code is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301; (2) pre-1978 articles, provided that the per-copy fee stated in the Publishers' Fee List is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301. Address requests for reprint permission to the Permissions Office, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1979: $60 domestic, $64 foreign, $6 single issue. APA member rate: $20. Write to Subscription Section, APA.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Published monthly in one volume per year by the American Psychological Association, Inc., 1400 North Uhle Street, Arlington, Virginia 22201. Printed in the U.S.A. Second-class postage paid at Arlington, Va., and at additional mailing offices.

Settings of a Professional Lifetime

Roger G. Barker
University of Kansas

This is a venture in ecocentric [sic] autobiography. Behavior settings important to the author during his 50 years in psychology are identified and described, circumstances of his entrances into and departures from the settings are reported, and immediate and enduring consequences for him are set forth. The article is a microsection of the history of psychology, 1928–1978.

I was Professor of Psychology and Department Chairman at the University of Kansas in Lawrence in 1948. On a particular day of that year, I worked on a research report in my Study at Home, answered correspondence, and made some phone calls at my desk in the Chairman's Office, met my Graduate Class in Experimental Social Psychology for two hours, conferred with the Dean of the College of Arts and Sciences in the Dean's Office, chaired a meeting of the Department Faculty, and attended a Departmental Colloquium; these six behavior settings made up my professional environment. During my life in psychology, which began, I shall presume, when I entered upon graduate study at Stanford University in 1928, and has continued to this day, the stream of my behavior as a psychologist has meandered through thousands of behavior settings. These settings have constituted the environment of my professional life, and in this article I shall describe some of their features and consequences for me.

The settings of my environment have had widely varying attributes; I have entered some of them by my own choice and have been coerced in varying degrees to inhabit others; in some settings I have had considerable influence, in others little power. The Chairman's Office differed greatly in these respects from the Experimental Social Psychol-

Editor's note. This is the second article on historical aspects of social psychological research. The series was begun under the general editorship of Anthony Greenwald; the action editor for the series is Irwin Altman.

This offspring of my life has benefited greatly during its long period of gestation and labor from the skills and encouragement of Irwin Altman and Phil Schoggen. In addition, Irwin Altman had an important part in its conception, and Phil Schoggen was presiding pediatrician after its premature birth. To them I extend my most sincere thanks. However, as its sole natural parent, I must answer for its defects.

Requests for reprints should be sent to Roger G. Barker, Box 98, Oskaloosa, Kansas 66066.

ogy Class: in the Office there was great diversity of both human and nonhuman components (secretaries, faculty, students, typewriters, telephones, files, people conversing, dictating, typewriting, and more), and all of these were incorporated into a relatively stable, multiform pattern of Office activities. In the Class there was less diversity (no secretaries, telephones, typewriters, files, people conversing or dictating) and a radically different, less complex standing pattern of lecturing, listening, and note taking. I entered the Chairman's Office by my own choice, but I was under strong compulsion to turn up for the Class at the scheduled time. I was powerless to change the program of activities of the Dean's Office, but I was able to alter the program of the Class, although my power was by no means unlimited. This setting had been a part of the College and the University before I joined the faculty, and they imposed certain features upon it that I was powerless to alter: I had to teach experimental social psychology, the setting's raison d'être (not ecology, a great interest of mine at the time), and I had to give grades (objectionable to me, but a policy of the University). Still, within these and other limits, I was in command of the program of activities.

When I have inhabited a behavior setting —whatever its attributes, the conditions of my entrance, and my power—I have become one of its component parts, and my behavior and experience have been formed by its ongoing program; these, therefore, have changed appropriately as I have moved from setting to setting. I did not pick up my mail or dictate letters in the Experimental Social Psychology Class or give lectures or quizzes in the Chairman's Office. The impress of some settings upon me has not extended beyond their boundaries; the stamp of others has been long-lasting. The influence of the Chairman's Office ceased abruptly at the door, whereas some attributes of my behavior and experience first occurring in response to forces within the Class have remained with me. In this account, I shall pay special attention to behavior settings that had long-continuing consequences for me.

Unfortunately the data I have to work with are poor. Few contemporaneous accounts of any setting are available, and still fewer are by independent observers. Most of what I am able to report is the fallible memory of how settings appeared to one inhabitant. In an attempt to mitigate the faults of the data, I shall confine my account to those settings for which there are contemporary data or very clear memories and that appear to have been crucial to my scientific activity. Fifteen behavior settings or clusters of settings most adequately meet these requirements. Here they are listed in temporal order of their occurrence and with their institutional connections: Stanford University, 1929–1935 (Terman's Seminar, Miles' Later Maturity Facility, Stone's Animal Laboratory); University of Iowa, 1935–1937 (Lewin's Offices, Nursery School Laboratory, Topology Meetings); Harvard University, 1937–1938 (Murray's Clinic, Child Psychology Class, Boring's Sack Lunch); University of Illinois, 1938–1942 (Study at Home, Extension Classes); Stanford University, 1942–1945 (Office of Disability Survey); Clark University, 1946–1947 (Office at the University); University of Kansas, 1947–1972 (Office of Department Chairman, Field Station in Oskaloosa).

I shall introduce each of these settings with its specifications under six rubrics: program, physical attributes, temporal characteristics, human components, powers of human components, and boundary properties. Then I shall report the forces and circumstances that brought me into them, the actions and experiences they elicited from me when I inhabited them and after I left them, and my power within them.

But first I must describe the 1928 person who was to make the trip through these behavior settings.

The 1928 Person

He was unsound physically, his intellectual powers were unknown, his financial resources were meager, his motivation was strong but unfocused.

An osteomyelitis infection of the left hip and right knee had had many acute phases since its beginning 12 years before. In 1928

the disease was quiescent, but acute episodes were a threat; a flare-up kept him out of school during 1929–1930. In its quiescent periods the disease was mildly debilitative, and its destruction of joints caused some locomotor impairment.

The 1928 person was 25 years old and 3 years behind academically. He attributed this to missing school because of illness, but he did not know what it signified for a career in science. Perhaps his isolation in sickrooms and his 6 instead of 8 years of secondary and college education handicapped him for advanced study; he was poorly grounded in mathematics and languages; he had studied no physics and had had only elementary courses in chemistry and biology. He remembered many evidences of intellectual marginality and inadequacy. There was his experience in the fourth grade, when the teacher could not decide if he belonged with the A group or the B group, so she had him sit alone between the elect and the scrubs. And he could not forget failing the first course in high school algebra, having to repeat it, and edging through the second go by memorizing the answers to likely problems, ending with the unanswered question: "How can it be possible to add, subtract, multiply, and divide letters, and why do it in any case?" Years later, too late to be of any comfort to him, he discovered that George Bernard Shaw had also had trouble with algebra, "mistaking the *a*, *b*, *n* and *x* for goods" such as eggs and cheese "with the result that I rejected algebra as nonsense" (Shaw, 1949, p. 41). Shaw blamed the instruction; "I had been made a fool of"; the 1928 person blamed himself. And there was his mother's aunt, an intelligent and insightful person, who was devoted to him during his adolescence and greatly worried about his future; she summed up her impressions of his assets and liabilities with the advice that he should prepare himself to be a short-order cook in a country restaurant. There was some evidence on the other side. There was the occasional, ambiguous remark about him by partisan adults: Still water runs deep. But this was less convincing than his great aunt's explicit evaluation. There was the thrilling time in the eighth grade when he was called upon to stand before the class and explain how to point off decimals in the quotient of a long division problem, and the teacher praised him. Having graduated from Stanford University with sufficient promise for the Psychology Department to accept him for graduate study would have been reassuring had there been entrance requirements; at least he was not discouraged by Professor Terman, the chairman. By far the most persuasive evidence, which tipped the scale in his self-evaluation, was the engagement between him and Louise Dawes Shedd. Louise Shedd knew him well, she herself had high scholarly credentials and bright goals for a life in the classroom and laboratory, and she was not about to link her life with that of a short-order cook. He was willing, in fact, relieved, to accept her evaluation, and he hoped to justify it.

His financial resources were less than zero, for during his undergraduate years he had accumulated hundreds of dollars in tuition loans that became due to the University in years immediately ahead.

Psychology for him was a means, not an end. His undergraduate introduction to the subject matter and methods of the science had no special appeal to him, but he believed it to be the least onerous route to his goal of "doing good" for mankind. He was a thoroughgoing, naive idealist and ardent reformer. He considered medicine but was sure he would not be accepted as a student, and his long, discouraging experience as a consumer of medical services had alienated him from the profession. He found economics too remote from particular people, and sociology too speculative and wordy. He tried to get a handle on demography but could discover no people or publications to inform him sufficiently about it. He did not consider literature, art, or the physical and biological sciences of any relevance to his goals. Psychology seemed to be a promising route, but even as he began graduate study he did not foreclose other routes, and within psychology's varied and vast domain, he had no preference. Although the zeal of the 1928 person was great, there were clouds on the horizon. He anticipated that the psychology route to good

works would have difficult and unpleasant stretches, and he was keenly aware of the likelihood of recurring acute phases of his illness. His prescience in the latter respect was verified by the flare-up in 1929–1930, and he hesitated about persisting, but for reasons impossible for him to comprehend to this day, his fiancee stood fast, encouraged him, and even married him in the summer of 1930. So in the autumn of 1930 he made a second start and became an anxious, vigilant, expectant psychologist in the making.

Stanford University, 1929–1935

I was a graduate and postgraduate student at Stanford University for 6 years. For 4 years I attended classes, did research under supervision, led "quiz sections" of elementary psychology, did various departmental chores (mimeographed class notes and exams, scored Strong Vocational Interest Tests, and cared for the animal colony), passed examinations, and received the MA degree (1930) and the PhD degree (1934). Being unable to find a regular position in the depression year of 1934, I was fortunate in being kept on as a research associate for 2 more years. The work was rewarding and the salary of $100 a month was satisfactory; with Louise's $1,800 a year as high school biology teacher we were able to pay my tuition loan debts to the University and save some money. Three behavior settings were crucial to me during these Stanford years.

Terman's Seminar

Program: Report by seminar member, usually a student, with interruptions by others discussing or questioning points made. *Physical attributes:* Locus, Terman's home on the Stanford University campus, in an attractive living room of sufficient size for a single-row circle of 25 persons. *Temporal characteristics:* Weekly meetings (with occasional skips) for about 2 hours during most autumn, winter, and spring terms; approximately 20 meetings most years. *Human components:* Dr. Lewis M. Terman, one or two other faculty members, occasional guests, 10–20 graduate psychology students. *Powers of human components:* Program determined at three levels of power. Terman's power extended over the entire setting (he selected the speaker, approved the topic, opened and closed the meeting); the speaker's power was supreme over the content and method of his report; the power of the other inhabitants was limited to supplementing, correcting, criticizing, and approving the speaker's presentation. *Boundary properties:* Admission at the invitation or urging (in the case of students) of Dr. Terman.

Reports usually described completed research or plans for research; occasionally books or monographs were reviewed. Almost all reports were concerned with research, emphasizing methods; theories or general issues were very rarely seminar topics. Interchanges between reporters and other members were usually for more information about procedures. The Seminar was eminently civilized and controlled, the occasional disagreements and arguments being muted. Terman set the tone, being quietly attentive, making few contributions himself other than introducing the speaker and ending the session with general remarks. Despite its appearance of tranquility, many students reported, outside the Seminar, that it was a tense, even traumatic experience for them. Many of the controlled interactions were undoubtedly reactions to the Seminar as a dangerous place for students; they were on trial before powerful present and future evaluators.

When Terman opened the Seminar to me, I eagerly attended. The name of the game for me was to learn as much as possible, to discover if I was likely to make the grade in scientific work, and to improve my chances of doing so by demonstrating what strength I had to Terman, the other faculty members, and my peers. The first and last intentions were not congruent. Optimal learning requires acknowledgment of ignorance, whereas putting one's best foot forward requires masking ignorance. And to walk on thin ice, as I did in the Seminar, always on the brink of both disaster and improved footing, is not conducive to a wide perspective and clear thinking; it is inhibiting. Still, one must act; to remain motionless on the ice, or dumb in the Seminar, is a sure way to disaster. Alert caution is essential. Under these circumstances motives and abilities and disabilities are not openly revealed, and valid judgments of persons are not possible, though reputations are made. I never knew my reputation among the

nembers of the Seminar, but I did know my elf-estimate. I placed myself near the median f the student seminarians, I was uncertain of assing the examinations, and I was quite ure my destiny was at best to become a ournеyman psychologist, perhaps in a junior ollege where, after all, there was plenty of cope for good works. Considering the people gainst whom I was judging myself, this self-stimation is not surprising; during the years f my attendance they included six who be-ame president of the American Psychological ssociation and a number of others who were onored by the Association for their scientific ontributions.

My immediate reaction after the Seminar as frequently one of great dismay: at my norance of what seemed to be common nowledge, at my failure to contribute what fterward appeared to me to be a valuable put, and at my espousal of weak, foolish, or relevant ideas. Louise came to dread the te-night aftermath of the Seminar.

I cannot now remember what I learned; I m quite sure that I encountered no mountain eaks of new understanding. But the Seminar rovided a regular update of what was hap-ening in psychology, especially with respect methods of investigation. More than this, became acculturated into the language, the ores, the ethos of the psychology tribe. And made acquaintances who have continued to e valued personal friends and influential onnections within the profession. On the egative side, I first encountered an aspect of cademic life that has continued to be dis-asteful to me: the ubiquity of judging others passing and failing students, approving and ot approving candidates, promoting and not romoting colleagues, accepting and not ac-epting research proposals, and so forth) and f being judged by others. The fact that most nterpersonal relations within Terman's Sem-nar involved, explicitly or implicitly, judg-nents of personal worth reduced its attraction s a social occasion and eroded its educational enefits.

Miles' *Later Maturity Facility*

Program: To study change in abilities from middle to later years of life. *Physical attributes:* Located near the central business district of Palo Alto in a one-time residence. The former reception hall, parlor, living room, dining room, and bedrooms were modified for use as offices and for administering tests and experiments; office furnishings and equipment for tests and experiments. *Temporal characteristics:* Operated weekdays for several months during academic year 1931–32 from 9:00 a.m. to 5:00 p.m. *Human components:* Walter R. Miles, graduate student research assistants, secretary, subjects. *Boundary properties:* Free access by staff; subjects admitted by appointment. *Distribution of power:* The power of Miles extended over the entire setting and program; he planned the research, secured the financing, selected the staff, recruited the subjects, approved the methods of testing and experimentation. The power of each research assistant was dominant within his laboratory room. The only power of subjects was to refuse to participate in a particular procedure; to my knowledge this did not occur.

I had completed my master's degree work under Miles with a thesis on finger maze learning, and it was now time to undertake research for the PhD degree. So when Miles returned from a trip East, bringing the news of a grant for the magnificent sum of $10,000 to support a study of old age, I eagerly embraced the opportunity to participate. For reasons I cannot recall, I chose to study muscular fatigue. Miles gave me complete freedom to devise a muscle fatigue test suitable for both robust 50-year-olds and frail centenarians, and I took considerable satisfaction in adapting a spirometer to determine hand and arm fatigue quickly. Other graduate students investigated changes in intelligence, learning, memory, motor skills, and sensory acuity. Subjects were recruited from clubs, churches, and living groups by paying the organization for each member who became a subject. They were brought to our experimental rooms by the secretary. At the time, I did not appreciate the luxury of having subjects provided to me with no effort on my part; many times since, I have appreciated Miles' efficient logistics.

I greatly enjoyed working within the Later Maturity Facility; the freedom within my own domain, and the straightforward problem were agreeable. I went home most nights feeling I was making progress toward providing some potentially useful new knowledge.

The more enduring consequences of this setting for me were, first, increased confidence

in my ability to engage in research on my own; after approving the area of my contribution, Miles took no part in my project; it became my own. Second, I learned something about the possibilities and difficulties of a kind of field study; I observed the extensive public relations activities required to secure subjects, and I was especially impressed with the effectiveness of approaching citizens by way of the organizations to which they were devoted. I also noted that the demands of public relations, at which Miles was very effective, divorced him from the details of the research. Because of this experience, I believe it was easier for me, when I later engaged in field studies myself, to realize that they require staffing different from that of laboratory investigations with captive or hired subjects and that community experts are as essential as observers, interviewers, testers, and so forth.

Stone's Animal Laboratory

Program: To investigate motivation in animals, chiefly rats, with emphasis on sexual behavior. *Physical attributes:* Locus, third-floor attic of the building housing the psychology department in an area partitioned into a sky-lighted animal room for about 100 animal cages, perhaps 10 small rooms for assistants and equipment, and Stone's large office. The equipment was primitive by present standards: student-made mazes, jumping apparatus, activity drums, Monroe hand calculators, simple shop equipment. *Temporal characteristics:* Functioned at some time every day. *Human components:* Calvin P. Stone, one or two postdoctoral fellows, two graduate assistants, several thesis students, a few students doing class projects, visitors. *Powers of human components:* Stone's power extended over the entire laboratory; he approved the fellows, selected the assistants, admitted the students and approved their research, set rules and standards. Fellows had complete power over their own research; assistants controlled their particular segment of the total program of the laboratory after consultation with Stone. Visitors' power was limited to viewing approved areas and asking questions. *Boundary properties:* Fellows, assistants, and students admitted by Stone personally; visitors were tolerated, but except for professionals, they were not welcomed.

As in 1931 (the opportunity to participate in the Later Maturity Facility came at a crucial time), I was fortunate in 1933 to be able to work in Stone's Animal Laboratory when I could not find a regular job. I did not choose to spend two years in this setting, but neither did I object; it was inevitable.

I found work in the setting even more satisfying than in the Later Maturity Facility. I had passed all examinations and written my thesis; that tension was gone. The intellectual camaraderie was congenial; postdoctoral fellows brought news and innovations from other laboratories; the pace of activities was not determined by tightly scheduled subject appointments. But there was a vigorous, steady program of activities; almost all the animal work required regular cleaning, feeding, observing, testing, and examining; Stone was a hard, regular worker himself, and everyone knew that he valued industriousness right along with honesty and intelligence. He was known to disapprove strongly of the policy of another university that reportedly provided technicians to do such detail work for graduate students as sectioning and preparing tissues for examination and running rats in mazes. In Stone's Laboratory, students cared for their own animals and spent the boring hours putting them through the necessary procedures. Inasmuch as Stone was in and out of the laboratory many times most days, beginning at 7:30 a.m., his power and reputation were sufficient to maintain a fairly tight ship without many definite rules and regulations.

Special emphasis during this period was on variation in the age of sexual maturity of rats, its genetic basis, and its relation to other behavior and somatic characteristics. Parallel investigations were conducted of the age of maturity of human females and its relation to their size and their interests and attitudes. I came to find much of the work interesting, and some of it had a permanent influence upon me. Even the evening after evening of testing young male rats for age of first copulation became enjoyable when Louise came along and read aloud from a high stool in the center of the animal room. (Conrad, Tolstoy, and Galsworthy in no way diverted the rat subjects from their putative activities.)

It was here that I first became aware of the potential value of archival data for psychological science. Stone was interested in the

intellectual level of children of abnormally early sexual maturity, and he had previously reviewed and summarized the literature. He set me to updating the survey, and I was impressed to find that although most evidence was in the form of reports of single or a very few cases, and none were adequate methodologically in terms of number and selection of cases and methods of testing, still, en masse, these data, reported by many independent investigators at widely varying times, in diverse situations and cultures, provided overwhelming evidence that early intellectual maturation does not accompany abnormally early sexual maturation. I noted that almost no cases were reported in the psychological literature, whereas medical journals served as valuable archives for these rare cases. I began to see that the insistence of academic psychology that every publication conform to all current canons of scientific adequacy was depriving the science of data on important issues. Years later I discovered a pair of identical adolescent twins, one of whom had been seriously crippled since childhood, and I saw this as an exceptional opportunity to obtain data from a very rare natural experiment on the effects of physique on personality; I studied them extensively. But I was advised not to attempt to get the material published because "one case means nothing." I wondered: Would a paleontological journal reject a study of 1 dinosaur egg because the investigator did not present data on 50 eggs? The lesson I began to learn in Stone's Laboratory has stayed with me, and I and my colleagues have not hesitated to collect "inadequate" data under certain circumstances, namely, when the problem to which the data refer is important, when fully acceptable data cannot be obtained due to their temporal or physical dispersion or their rarity, and when the data are such that investigators at other times and in other places can add to them.

It was in Stone's Laboratory that I first encountered a set of problems that have occupied me ever since, namely, environmental influences on behavior. At the time, however, I did not see the particular problem in this context. It arose from our studies of relations between age at menarche and physical and social development in girls. We discovered that in the early adolescent years, early maturing girls are more similar to older females in measurements of physique than are late maturing girls of the same chronological ages, and when we asked if this same relation holds for social interests and attitudes, we found that it does: Postmenarcheal girls 12, 13, and 14 years of age are more similar to older females in their responses to interest and attitude test items than are premenarcheal girls of the same ages. So we faced this question: To what degree are the differences in attitudes and interests due to direct hormone influences, and to what degree to the fact that the physiques of the early and late maturing girls provide the girls and their associates with stimuli with different social significances, thereby imposing different social environments upon them? We could not answer this question with the data at hand. Five years later, at the University of Illinois, I returned to this problem and found evidence that powerful adults (parents, teachers) bring greater pressure upon physically mature girls to engage in mature behavior than upon physically immature girls. And 10 years later, when I was back at Stanford, I returned to the problem in connection with studies with my students of the psychological consequences of physical crippling.

In addition to initiating this particular continuing interest, Stone's Animal Laboratory further strengthened an attitude I carried with me from other Stanford settings, namely, that strong and persisting but rather narrow programs of activities are productive. There were no brilliant performances at Stanford. The research of Terman on the gifted, of Stone on animal motivation, and of E. K. Strong on interests yielded no remarkable breakthroughs, but they were and have continued to be recognized as substantial achievements. This was not an "Aha!" experience for me; but as I look back I can see that it became a deeply rooted conviction that this was to be my way of doing science. Along with this vaguely developing insight there was increased self-assurance. At the end of my 6 years at Stanford, I was more sure that my aspirations for a productive career in science

were not hopeless. However, I did not have a strong commitment to any problem. I had worked on a rather wide range of problems via a considerable number of methodologies, but I had become devoted to none. I was still unfocused, at the beck and call of almost any opening that would allow me to earn a living as a psychologist. In the spring of 1935 an opening came that radically altered my intellectual lifestyle and threw me again into uncertainty about myself.

I took part in many behavior settings at Stanford other than the three I have described: classes, lectures, seminars, laboratories, projects, examinations. They enriched my intellectual life and widened my perspective, but only one of them had particular, identifiable consequences for me. This setting channeled the stream of my behavior as a psychologist into its first great bend. Kurt Lewin came as a visiting professor for the year 1932–1933. I was very busy during this year finishing my doctoral thesis so I was able to attend Lewin's class only as a visitor. He attracted me greatly as a person, but his psychology confused me or, perhaps more correctly, it was incomprehensible to me. Fairies and ectoplasm would have been more comprehensible than life space, valence, psychological force, inner-personal regions, substitute value, psychological satiation, and so forth. Stanford students knew something about Gestalt psychology experiments and theories of perception from the writings of Wertheimer and Köhler, and of development from the works of Koffka, but Lewin's so-called Gestalt psychology seemed to have nothing to do with these, as we expected. And equally disconcerting, Lewin seriously reported experiments with seven subjects, and instead of replicating the experiments, he changed the conditions; even worse, if the results from the altered conditions were in accord with his predictions on the basis of theory, he took this as a verification of the findings and the theory. I suppose Stanford University in those days was among the least auspicious places in the United States for an understanding of Lewin; theory was almost a nonword in the psychology department, although we did use it in connection with Spearman's interpretation of intelligence test intercorrelations (theory of general intelligence) and we read about psychoanalytic theory. But most of us had no background in the philosophy of science, and the place of theory in science. So Lewin's *Dynamic Theory of Personality*, which I reviewed (with Terman) and which he taught in his course, was a transient foreign body, a UFO, to most of us. I cannot recall that any of the students who attended his class took and retained a serious interest in his viewpoint unless they had later association with him. The gulf was too wide to be bridged quickly, and the dissonance was so great that some rejected his ideas out of hand. I was not negative; I was tolerantly baffled.

So when the opportunity arose to join Lewin as a General Education Board Fellow at the University of Iowa for the year 1935–1936 I was intrigued; here was a chance to learn a different kind of psychology, to earn a full living for Louise and me for the first time, and to have the prestige of the fellowship. Indeed, I had no choice; circumstances beyond my knowledge and control were turning the stream of my professional behavior, indeed my whole life, in a new direction. I have no idea to this day how my nomination to this fellowship came about, but I am sure that an important factor on the Stanford side must have been: It is really time for Barker to push off the home place. I thought so, too.

University of Iowa, 1935–1937

Kurt Lewin went to the Iowa Child Welfare Station in the autumn of 1935 on a grant from the General Education Board, with provision for three research assistants. The first assistants were Tamara Dembo (who had been a student of Lewin in Berlin), Herbert F. Wright (who had been a student of Donald K. Adams at Duke University; Adams had studied with Lewin in Berlin), and me. My fellowship was extended in the spring of 1936 for 1 more year. Three behavior settings were of primary importance to me at Iowa.

Lewin's Offices

Program: To plan the research project we would undertake, and to discuss and make decisions about

rocedures and problems when it was underway; to nalyze data from the project and write up reports; o read the writing Lewin was doing, to listen to his roposals for reformulations and additions, and to riticize and make suggestions. *Physical attributes:* ocated in four adjacent office rooms on an upper loor of East Hall, University of Iowa campus; he building had been a hospital and the rooms were ormer single-patient rooms; they were a little rowded with a desk, a bookshelf, a blackboard (in ewin's office), and four chairs when we were all resent in a single office. *Temporal characteristics:* n operation at some time almost every day, with ne or more participants; sessions with Lewin oc- urred whenever the project needed his attention and henever he had something to discuss. *Human com- onents:* Lewin, the three assistants, frequent vis- ors. *Boundary properties:* Assistants selected and dmitted by Lewin; free entrance for visitors. *owers of human components:* Lewin established he program of the setting; he decided that the re- arch would be upon frustration, but the details of rocedure were worked out in group consultation, here he was first among equals; he was, of course, total control of his own writing, the assistants erving more as persons upon whom he could try out is ideas than as consultants or collaborators, al- hough he took seriously all criticisms and sugges- ons.

It is difficult to imagine more different cli- nates for scientific work than those obtaining t Stanford and at Iowa. At Stanford, science athered facts about behavior via experiments nd tests, determined their central tendencies, nd analyzed their interrelations; in Lewin's etup, science explored ideas about behavior ia experiments and observations. At Stan- ord, conclusions were in terms of the means, ispersions, and correlations of samples of *acts* about behavior; my own work discov- red that the rate at which 80-year-olds pump ir into a spirometer declines faster during a ork period than the rate at which 50-year- lds pump air. At Iowa, conclusions were in erms of verified or altered *ideas* about be- avior; in our work there we found (in ac- ordance with a theory) that in psychological rustration, inner-personal systems can be con- idered to be in a state of blocked tension that mounts to functional dedifferentiation, one xpression of which is lowered level of intel- ectual activity, that is, intellectual regression.

In the beginning, the sessions in Lewin's ffice were an ordeal for me; they were be- wildering and tiring. The ideas we were to explore and clarify in connection with the frustration study were too unfamiliar for me to make many contributions; as for the monograph Lewin was working on, *The Conceptual Representation and Measurement of Psychological Forces,* the ideas were utterly baffling. Lewin's eagerness and the energy to back it up seemed boundless, whereas the tension and alertness of the 2-hour sessions of Terman's Seminar left me dog-tired; after meeting with Lewin, Dembo, and Wright from 2:00 to 7:00 in the afternoon (with Lewin reading aloud what he had dictated the day before, interlining new sentences, rearranging the order, violently objecting to a criticism by Dembo, turning to Wright—"Herbert, is she right?"—accepting Dembo's criticism, diagramming a relation on the blackboard, crossing the whole page out, dictating a new version to Dembo, and so forth), I was ready to drop. After five o'clock I would hope beyond hope that my dear, pregnant wife, lonesome at home, would telephone that I was urgently needed. Sometimes she did. A frequent concluding remark by Lewin was "We must think about this," and that after 3, 4, 5 hours of nothing else. Did this add up, perhaps, to a kind of brainwashing? In any case, as the months went by, I began to understand Lewin, and his ideas have remained at the center of all my subsequent work. But equally important to me has been the new, higher level of intellectual effort to which I became adapted. I could never come close to Lewin's intensity; I had to take it much slower, but his refrain, "We must think about this," has stayed with me. Although no one could have been more subordinate to Lewin in terms of knowledge, I was always treated as a colleague, never as a pupil. My contributions, however naive, were always taken seriously, Lewin often seeing in them more than I had intended.

Nursery School Laboratory

Program: To carry out the research on frustration, we planned in the offices in East Hall. *Physical attributes:* Two ground-floor rooms in a remodeled residence across the street from the station's nursery school equipped with a one-way observation booth, child-sized chairs and tables, toys, and a movable barrier in accordance with the research design. *Temporal characteristics:* Setting occurred intermittently during winter and spring of 1936–37, according to a

schedule of appointments. *Human components:* Tamara Dembo and myself, alternating as observer and experimenter, and a single child from the nursery school at each occurrence. *Boundary properties:* Free access to Dembo and me; child subjects, a different one on each occasion, selected and required to attend in accordance with decisions made by us and nursery school staff. *Powers of human components:* Dembo and I had joint authority over the entire setting, although, according to the experimental design, we did not intrude into regions designated for free play; child subjects had no power except in designated free play regions.

Basic to much of the early research Lewin initiated is the theory that psychological tension systems correspond to intentions to engage in molar actions. The studies of interrupted and substitute tasks issued from this theory. Lewin came to Iowa with the intention of investigating this idea further; he thought that the undischarged tensions that occur in frustration result, via increased rigidity and spread of tension to adjacent regions of the person, in functional dedifferentiation, and that one manifestation of this is intellectual regression to a state normal for an earlier age. The problems for the assistants were to devise a frustrating situation and methods of assessing intellectual level inside and outside this situation. The nursery school setting in which we worked on these problems elicited from me two insights that have remained with me. I discovered the value, for studies of molar actions, of situations where the investigator intrudes not at all or very little, and the value of detailed narrative records of behavior. The frustration study involved, for the most part, a continuation of the child's usual nursery school day, and in his free situation, we were able by means of nonintrusive narrative records to assess intellectual level as accurately as formal intelligence tests do. In later work, my colleagues and I have come to depend very extensively on narrative records of behavior in situations that are completely free of our influence; and we continue to be impressed with the value of ordinary language as a coding system for the subtleties and complexities of behavior. The Nursery School Laboratory was a welcome refuge for me from the conferences in Lewin's Office. Here I found a kind of therapy in applying my Stanford expertise to the gathering and analyzing of masses of data.

Topology Meetings

Program: To discuss Lewinian theory and research findings. *Physical attributes:* Occurred in academic conference rooms of various universities. *Temporal characteristics:* Took place during Christmas vacation for two or three full-day and evening sessions. *Human components:* Lewin and invited guests; the latter were former and present students and colleagues, and a few others interested in Lewin's ideas. *Boundary properties:* Invitations issued by Lewin and by people at host school. *Powers of human components:* Designated persons at host institution controlled local arrangements, Lewin arranged program of papers; free discussion.

The Topology Meetings were as much a part of my Iowa experience as were Lewin's Office and the Nursery School Laboratory, even though the meetings were held at Cornell University and Bryn Mawr College in those years. They agitated me somewhat as Terman's Seminar had, although the testing aspect was less pervasive and the learning aspect more pervasive; still these settings were new and strange, and I was alert and cautious. In them my world expanded greatly, to encompass many new friends and acquaintances, many new concepts applied to new problems, and many new locales and institutions (I had not previously been east of the Mississippi).

The adjustments I made to the three crucial behavior settings at Iowa were only part of the intellectual turmoil I experienced. There were other upsetting settings. In some of them Herbert Feigl expounded physicalism and the views of the Vienna Circle; in others, Spence's kind of Hullian behaviorism was expounded. Iowa, for that brief time, at least, was a bubbling cauldron of antagonistic ideas. With my nontheoretical background, I was severely buffeted by the strongly asserted convictions of these sophisticated advocates. Lewin's handling of these disturbances impressed me and has been a model for me since. Although he defended his viewpoints strongly, he was not rigidly partisan. An early remark he made to a student objector at Stanford, when his English was poor, expressed his position:

Con be, but I sink absolute uzzer." He did ot think current controversy would settle asic issues, that only empirical evidence ould in the long run sift the true from the lse, and that the business of science was to et ahead with empirical tests. He strongly xplored the disruptive partisanship within erman psychology.

Before the end of my second fellowship ear a new opportunity arose that I could not ecline: an instructorship at Harvard Uniersity to teach a course in child psychology. s with the General Education Board Fellowhip, I have no knowledge of the forces that rought this opportunity to me. But again, fter 9 years, the stream of my professional ehavior was to flow in a ready-made chanel. Previously, the Later Maturity Facility, he Animal Laboratory, and the General Edcation Board Fellowship had taken charge f my life in psychology, and now the Harvard sychology Department took over with no ffort by me. But there was a difference: Whereas previously I had been in the role of upil (to Terman, to Miles, to Stone, to ewin), now I was to be on my own in my eaching and in my research.

Harvard University, 1937–1938

I arrived at Harvard under the cloud of an lness, not my old familiar trouble, but susected appendicitis. I presume now, more han I admitted then, that the symptoms were f psychosomatic origin. And why not? I was onfronted with the task of teaching a subject ew both to me and to the Harvard Psychology Department (Child Psychology had not een in its curriculum before) to hypercritcal Harvard students (Boring warned me of hem in a letter in which he also expressed he concern of the Department about its repitation among undergraduates for good teachng) before the eyes of some of psychology's op brass (Boring, Allport, Murray, Lashley) nd its brightest lieutenant colonels (S. S. tevens, B. F. Skinner, Robert W. White).

Murray's Clinic

Program: To carry out studies of personality; the program was minimal this year, however, as Murray was on sabbatical leave. *Physical attributes:* Located in a converted residence on Plimpton Street, a block and a half from Emerson Hall, headquarters for the Department; clinic office, staff offices, library, experimental rooms, shop, kitchen; the library and several offices were elegantly furnished with fine rugs and period furniture. *Temporal characteristics:* In regular operation weekdays and at any time for particular staff members. *Human components:* Acting director, three or four staff and/or psychology department members, a postdoctoral fellow, several students, clients and subjects, secretary, shop man. *Boundary properties:* Free access to official personnel, clients and subjects by appointment. *Powers of human components:* The acting director was Robert W. White, who had final control of the entire setting, although staff members and the fellow were quite independent; the secretary and shop man were semiautonomous within their areas; powers of clients and students were limited by the staff members with whom they were associated.

Murray's Clinic was my salvation: It was leisurely and quiet; my office was large, with comfortable chairs and a couch; after the hectic pace at Iowa, it was a refuge. Here I could sit and think about where I had been and where I was going, emerging only at intervals to grapple with my one class. Part of where I had been was with me in the form of a partially completed manuscript about the Iowa frustration experiment; sitting on my desk in a big box, it was a continual irritant, but it did not claim or oppress me. I tested where I was going by doing an experiment on conflict resolution; it was a Lewinian experiment and it was congenial to me, but I did not see it as a channel to a lifetime of research; I did only one other study of conflict. I believe I became dimly aware, then, that further investigation of conflict resolution would lead to finer grained and more complex theories and more detailed and precise experimental procedures that did not suit me. This may have been the beginning of my aversion to the reduction of theoretical explanations of molar events to theories of their more molecular components, with the implication that the latter are the more fundamental. Murray's Clinic was my first experience of a behavior setting without a coercive program. Whereas the settings at Stanford and Iowa took me in hand and put me through their paces, Murray's Clinic protected me from impositions. Settings of this kind have fortu-

nately occurred at regular intervals in my career.

Child Psychology Class

Program: To teach child psychology to undergraduate students. *Physical attributes:* Classroom for about 40 students in the basement of the Clinic; chairs, podium, blackboard; furnishings and decorations somewhat shabby. *Temporal characteristics:* One hour's duration, three times weekly for one semester. *Human components:* Instructor and 35 students. *Boundary properties:* Access only for instructor and registered students. *Powers of human components:* Program under complete control of instructor; powers of students limited to expressing approval or disapproval.

The sensitivity of the Psychology Department to the students' regard for the teaching it provided caused me to approach this, my first teaching, with more than my usual trepidation. I worked hard welding my Stanford and Lewinian background into what I am sure was a unique course of study. There were a few rough places in this setting, marked by some foot shuffling, but it ended with an acceptable round of applause. So I emerged with some confidence in my teaching ability and with a course outline that was a long-time asset.

Boring's Sack Lunch

Program: To combine an economical lunch with friendly conversation among colleagues. *Physical attributes:* Locus, Boring's office in Emerson Hall; table around which eight people could sit comfortably; sack lunches; in the background a desk and shelves filled with books. *Temporal characteristics:* 1:00 to 2:00 p.m. most weekdays. *Human components:* Boring and, usually, five or six staff members and visitors. *Boundary properties:* Access at Boring's invitation. *Powers of human components:* Boring's benign influence pervaded the setting.

I was flattered to be invited. I expected stimulating conversation of the kind I had heard took place at the high tables in the English colleges, but in this I was disappointed. Despite the high caliber and great achievements of a number of the attenders (B. F. Skinner, S. S. Stevens, Boring, occasionally Lashley and Beebe-Center), small shoptalk about equipment, library resources, particular research results, publishing problems, together with bantering but restrained gossip about current university, community, and national affairs prevailed. I emerged from this setting with some impressions of eminent and soon-to-be eminent people, but nothing of professional value to me. It did strengthen my belief, originating at Stanford and strengthened at Iowa, that the effective men in the science were blue-collar, hard-hat workers, not gentlemen scholars. Here was Boring, well past middle age, the Mr. Psychology of the profession in America, eating his cold egg sandwich with the boys and discussing the nuts and bolts of research and writing, not lunching gracefully in the Harvard Faculty Club with his professional and administrative peers on the Club's famous horsemeat steaks.

My time at Harvard was one of greatly expanded perspective, not of psychology as a field of study, but of the people, institutions, and cultural milieu of the science. Other settings that contributed to this expansion were conferences sponsored by the Macy Foundation, where I encountered the eastern wing of the child development movement and for the first time directly heard psychoanalysts expound their views.

Although I was no longer in the role of a student, I was still a probationer. As I understood the Harvard policy, it was: 3 years at most as an instructor and then up or out. As I saw no possibility of my moving up, I determined before the end of the year to seek another position. Behind this decision there were a number of considerations: uncertainty if I would be appointed for a second year and apprehension about finding a place in 2 or 3 years, when I would need one; the belief that 9 years as apprentice (6 years at Stanford, 2 at Iowa, 1 at Harvard) with the continual strain of being tested was enough; and the realization that I was veering sharply away from my goal of using psychology for the direct benefit of people. So when I heard that a position as Assistant Professor of Educational Psychology was open in the College of Education at the University of Illinois, I applied for it and was appointed. As it turned out, another year at Harvard was offered to me, and some surprise was expressed that I

chose Illinois. But Louise and I went with few regrets; we were at last taking a hand in the direction of my professional career, our economic future did not come to a dead end in 1 or 2 years, and education was surely a promising place to apply what I had learned at Stanford and Iowa.

University of Illinois, 1938–1942

We arrived in Urbana, Illinois, in July 1938 with our 2-month-old and 2-year-old children. We rented a house while looking for one to buy; we were ready to settle down.

Study at Home

Program: To get on at last with my own version of psychology. *Physical attributes:* We soon purchased an old house from a retired academic who had made himself a study to match, on a small scale, the library on Plimpton Street: paneled walls, a fireplace that worked, many shelves, stained glass windows, space for a large desk and work table. *Temporal characteristics:* Occurred at my discretion during the Illinois years. *Human components:* Myself, my students, Louise, and our children. *Powers of human components:* I was in overall charge, but in these years Louise began to participate in the research, a partnership that has continued, with some breaks when she has had outside jobs. *Boundary properties:* Penetrable to me, Louise, and children at any time; to students on invitation.

What I had prepared for the Harvard students of child psychology seemed good enough also for the Illinois students of educational psychology, so I turned early from preparations for my class to other undertakings. Two of these were rooted in Stone's Laboratory, two in Lewin's Offices, and one was a "do good" effort.

The question of whether differences in the attitudes and interests of premenarcheal and postmenarcheal girls have a basis in the social significance of their different physiques was left unanswered 5 years earlier, so I returned to it now and found evidence that, indeed, the adult associates of mature adolescent girls provide a different (more "mature") social environment for them than they do for immature girls. And I expanded my concern for the environmental significance of physique to physically disabled people and asked if they also live in a different environment from that of physically normal people by reason of their physiques. I began a long involvement with this question with two case studies. Although the roots of my interest in the environmental significance of physique were in Stone's Laboratory, my interpretations and theories came from Lewin's Office, and undoubtedly my expansion of this interest to physical disability was influenced by my personal experience with the problem.

The unfinished manuscript of the frustration research still occupied a prominent place on my desk, and I continued to wrest time from more immediately interesting new tasks to inch along toward its completion. And the conflict resolution study had become such an uncompleted task for me that I was impelled to replicate (and verify) the findings by an entirely different method.

My "do good" effort was carried out in collaboration with Herbert F. Wright, my fellow Fellow at Iowa, and Jacob S. Kounin, my new colleague at Illinois. This was a collection of reports of psychological research in the field of child development. It was intended to provide a "bookshelf" of primary research for students of child development and thereby promote scientific child study as a field for both practitioners and scientists. It is my impression that this was the first "reader," as they are now called, in child psychology, and perhaps in psychology as well (Barker, Kounin, & Wright, 1943).

My Study at Home was not only a place to get on with my version of psychology as a science; it became a place to teach my version, as well. In the early autumn of 1940 an acute phase of the bone infection occurred, and I was completely incapacitated for the term. Jack Kounin came to my rescue, taking over my classes, presumably for a short time. But as it turned out, I was out of commission for 4 months. Due to Jack's heroic efforts and the tolerance of the College and University, my pay continued. In the second semester, although still in a full body cast, I was able, again with the kind indulgence and special arrangements of the College, University, and students, to meet small classes in my Study at Home. Perched on a high tavern-type chair

within a specially built surrounding pulpit, I was able to expound the word to a score of students at a time.

Again, as with Murray's Clinic, my Study at Home saved me from possible disaster. This one nourished projects I brought to it from Stanford and Iowa, and in it new, long-continued undertakings originated.

Extension Classes

Program: To teach educational psychology at the graduate level to primary and secondary school teachers. *Physical attributes:* Located in classrooms of state teachers' colleges, which did not at that time offer graduate-level instruction. *Temporal characteristics:* Occurred on Saturday mornings for two hours during each semester. *Human components:* Instructor and 20 to 40 students from the schools of the area. *Boundary properties:* Only students satisfying registration requirements of the University were admitted. *Powers of human components:* Program controlled by instructor.

The Saturday trips from Urbana to outlying teachers' colleges, usually by automobile but in some cases by train, were enjoyable and satisfying. The mature, practicing teachers brought me into contact with real teaching problems in the towns where they taught; they educated me perhaps as much as I educated them. And the trips revealed to me something about the rural Midwest. I was intrigued with the small towns, and elsewhere I have related how the general problem that dominated the last 25 years of my professional life occurred to me as I was rushed through them by the train on the trip from Urbana in the center of Illinois to Carbondale in the south (Barker & Associates, 1978). In short, I had an overwhelming *negative* "Aha!" experience: Here I was, a native of the culture and an expert on child behavior (and especially on frustration) who knew no more about the everyday behaviors and environments of the children of the towns than laymen know. I was aware, too, that other child psychologists knew no more than I did, and furthermore, that we had no means of discovering more; no methods of determining the extent and conditions of frustration, joy, anger, success, conflict, problem solving, fear, and so forth among the towns' children. I thought how different the position of an agronomist would be. He would know or could determine the kinds, yields, and qualities of the crops we were passing, the properties of the soils in which they were growing, and the relations between soil conditions and output. This was the beginning of a growing conviction that a science that knows no more about the distribution in nature of the phenomena with which it is concerned than laymen do is a defective science, and it was the beginning of my impression that small towns of the kind I observed in Illinois and learned about from the teachers are favorable places to begin to remedy the defect. It was seven years before the seed planted in the Extension Classes and on my trips across the plains of Illinois began to sprout.

It was not long after we went to Illinois to "settle down" that irritants began to appear. There were the disagreeable administrative impositions upon my teaching that finally became intolerable to me. And I was soon to discover that my flight from a marginal position vis-à-vis the upper uppers of the profession at Harvard had landed me squarely with the lower lowers. I attempted to establish collegial relations with psychologists in the Psychology Department but without success. Part of the difficulty was structural: I was separated from them spacially, temporally, and administratively; I was in a different building, their seminars and other gatherings often conflicted with my staff meetings and other duties, and administrative messages were on different communication networks. And in addition, I found that a psychologist in a college of education is distinctly lower-class. This so impressed me and it was so important to me personally that I used my experience as evidence for an analysis of the values and dynamics involved. Finally, I became discouraged about my ability to combine scientific work with applications. I began to see that it required more than clear lectures to alter the practices of teachers. My own experience, namely, that because of impositions from the encompassing system I could not practice in my own teaching at the University, the principles that my science showed me to

be true should have made this immediately clear to me, but it took time. I struggled on with increasing dissatisfaction. Finally, in the spring of 1942, these multiple environmental stresses became so great that I wrote to Terman telling him of my disenchantment. To the surprise and delight of both Louise (who, surprisingly, did not thrive with a troubled mate) and me, Terman answered immediately with the offer of a place at Stanford for the duration of the war.

At Illinois I learned some important things about myself and about my profession; I closed out some unfinished tasks and initiated some new ones. I look back on the time there as a rough but beneficial passage.

Stanford University, 1942–1945

The Stanford appointment was as Acting Associate Professor. I understood clearly that this was an emergency appointment to bolster a war-depleted staff. At the time its temporary nature did not trouble me or Louise; the advantages were many: I was free to teach as I pleased (the motto for Stanford of its first President, David Starr Jordan, "The winds of freedom are blowing," was fully realized in the classrooms of the Psychology Department); I was again a member of psychology's upper class; we were home among friends; Louise was welcomed back on a part-time teaching basis to her old school; my health was on the upgrade and promised to improve more in the California sunshine. We were in such good shape, in fact, that our third child was born in the spring of 1943. Furthermore, it turned out that I was able to make an important immediate application of my psychological knowledge.

But not all was rosy. The war was ever present on the West Coast, with blackouts, shortages, relatives and friends embarking for Asian combat, and casualties disembarking. The teaching load was heavy; in addition to the regular offerings, short cram courses were given for officers in training. I taught a number of subjects new to me, so I had to do much homework to keep ahead of the classes. Most of these 3½ years at Stanford were a steady grind. Only one setting stands out as of special significance for my career. It came about through a fortunate conjunction of (a) my desire to make a contribution to the war effort; (b) the national need for rehabilitation service for war casualties; (c) my interest in, my exploratory research upon, and my personal experience with, physical disability; and (d) resources that the Social Science Research Council (SSRC) made available. A crucial person in tying together these separate strands was my colleague Quinn McNemar, who was a member of the relevant SSRC committee; it was at his instigation that the Council funded the preparation of a survey of what was known about the psychological aspects of the rehabilitation of the physically disabled (Barker, Wright, Meyerson, & Gonick, 1953). I set up a special study at home for this project.

Office of Disability Survey

Program: Preparation of monograph *Adjustment to Physical Handicap and Illness. Physical attributes:* We were living in a house built by Walter Miles, my former professor and thesis adviser, which had a fine, spacious, isolated study; it became headquarters for the monograph project. *Temporal characteristics:* Occurred whenever I had time during the years 1943–1945. *Human components:* When the magnitude of the project became clear, I was fortunate in obtaining contributions from Beatrice A. Wright, Lee Meyerson, and Molly Gonick. *Boundary properties:* Ready access by the four participants. *Powers of human components:* Overall control was in my hands; others had complete autonomy for their own contributions.

In this setting I experienced some of the great satisfactions of my professional life, and they have continued to this day. In the first place, I felt competent; I believed I was as able any anyone to do the job at that time. Second, I saw this as my first opportunity to bring my skills to bear upon an urgent practical problem. As it turned out, the time was ripe for this; beginning with World War 2, concern and services for the disabled have increased greatly, so any firm foundations laid in 1943 have had continuing consequences. And third, I believed at the time that I was able to contribute to this firm foundation by pointing out that some psychological problems of the disabled are not unique to them, that

adolescents and ethnic minorities, for example, face the same problems; I was able to do this in terms of Lewin's concepts of marginal men and overlapping situations. I have not followed the course of rehabilitation psychology in recent years, so I have no firsthand knowledge of the permanence of this contribution, but I am told that the monograph is still in demand. Clearer evidence of the enduring consequences of the Disability Office is the fact that both Beatrice Wright and Lee Meyerson have become leaders of this field of psychological study.

In 1945 I wore the child psychology label, primarily, and there was not much demand for this branch of the science at Stanford. Members of the Department had ambitions to develop a program of studies in child psychology, but money was scarce and progress slow; their principal efforts went to accommodating regular staff members returning from war service and to filling vacant, established slots. So in October 1945 I was told that there was no hope for me beyond the next spring semester. As of June 1946 I would be through at Stanford. The likelihood of this subsidence of the stream of my professional life had long been within my time perspective, but the reality was more vivid than the distant prospect. It gave a new urgency to the somewhat relaxed inquiries I had initiated before reality descended. I had communicated about possible jobs with a number of schools, including Clark University, and in the summer I had an interview with President Atwood about the vacant G. Stanley Hall Professorship in Child Psychology. I did not take this possibility seriously. So, when a definite offer came from Clark in November, Louise and I were almost overwhelmed by the drastic alteration in our prospects. But we were able to make the transfer; we arrived in Worcester, Massachusetts, for the second semester in January 1946.

Two firsts of some importance occurred during the 3½ years at Stanford. One was advising graduate students on their thesis research. In line with my interest in the disability problem and my work on the survey, three students undertook theses on attitudes toward the disabled. The other first was the establishment of the Disability Survey Office as a major behavior setting with a program after my own specifications; until this time, apart from minor side excursions, I had operated in behavior settings with programs arranged by others. At Stanford I was born as a psychologist, and on my return 15 years later I gained these two evidences that I had at last reached my majority.

Louise and I left Stanford older and with more experience of the stream of university life. We had drifted through the dangerous, white waters of Harvard, portaged to the slow Illinois channel with its sandbars and driftwood, portaged again to the steady, full flow at Stanford, on whose banks we were briefly stranded until an unexpected flash flood carried us to Clark. One more portage was to come.

Clark University, 1946–1947

Clark turned out to be a bayou for us. The top administrators changed six months after we arrived, the psychology department had been understaffed for some time and had an acting chairman, and I was uncertain of the direction of my next efforts, having completed the disability monograph. With so much in the process of change, all of us—the University, the Department, and I—marked time. It was now that the seed planted in my mind on the plains of Illinois began to grow, and I seriously considered a project to discover and describe the living condition and behavior of the children of a small town. I took two actions. I explored the towns around Worcester, and I discussed the project with Kurt Lewin, who was then at the Massachusetts Institute of Technology and was living only 30 miles away. The exploration was discouraging. The small settlements of the region were not self-contained towns as in the Midwest; they were spacially dispersed and often specialized fragments of political units (towns) often straggling many miles along streams or across forested ridges. The children of these fragments did not have a common community environment as did the children of the towns I had seen in Illinois. But the discussions were encouraging, and in fact Lewin was enthusiastic. He, himself, was moving from lab-

oratory experimental research to "action research" in communities and institutions to study the consequences for the inhabitants of induced changes in their structures and programs. So he was supportive of efforts to establish baselines in unaltered communities against which to assess the effects of changes. With his encouragement, I worked on an application for funds for a community study with the intention of doing the research at a distance from Worcester if necessary.

And now luck was with us. The United States Public Health Service was expanding its support of basic research, particularly on children. The advisory committees included persons familiar with my work whom I had met at Stanford, Iowa, Illinois, and the Macy Foundation and Topology Meetings. The project was approved, and the research was funded early in 1947. And then Dean Lawson of the University of Kansas turned up in Worcester. He was looking for candidates for the chairmanship of their Psychology Department. The department was at a low ebb, and the administration was ready to make a new beginning and provide the support required to bring psychology at Kansas to its former rigorous state.

Why should I be interested? I had just come to Clark, to an endowed professorship with some status and to a department that also was set to make new beginnings. One could interpret my career as exhibiting clear signs of instability; a solid and frank New Englander, on hearing from Louise of the towns in which we had lived, remarked, "I see your husband is something of a floater." Surely it was time to settle in and stay on course. But there was the research and the dispersed Massachusetts towns. I told Dean Lawson of the project and the kind of town it required. Did he know of such a town in the Lawrence area? "Yes," he said without any hesitation, "I know the place. I've spoken there several times. Its name is Oskaloosa." I made two trips to Lawrence that spring; on the second trip I asked my former fellowship colleague at Iowa, Herbert Wright, to come along and consider joining in the department and the research. We visited Oskaloosa. He came and he joined. So Louise and I made one more portage.

University of Kansas, 1947–1972

We arrived in Lawrence in late August 1947 in a 115° heat wave. But, no matter, important things were underway. Fritz and Grace Heider were joining us, along with Herbert and Lorene Wright. There were houses to rent, a new department office to establish, instructors, teaching assistants to hire, and the University's rules and regulations to master.

I learned slowly why I had been chosen for this job over some other strong candidates. G. E. Coghill, a stellar name in biology in those days, had recently retired, and psychologists Raymond Wheeler, F. T. Perkins, and J. F. Brown had lately left the University. All of these men were well known for their "organismic" viewpoints. It was the wish of the two regular staff members who remained, Beulah Morrison and Anthony J. Smith, and of the administration, that this tradition be continued. Without making this explicit, Dean Lawson apparently saw that I would do this naturally and with enthusiasm. And in fact he had two immediate signs of the correctness of his insight when I recruited Herbert Wright and Fritz Heider within a couple of months. In the next three years we added Martin Scheerer, Alfred Baldwin, and Erik and Beatrice Wright. The new senior staff members were all from the center or the fringes of the Gestalt psychology movement.

Two behavior settings dominated my professional activities over the next 25 years; one of them was of my own creation, and I had considerable power over the other.

Office of Department Chairman

Program: To invigorate and expand the psychology department and to establish and administer settings subordinate to it according to University and Staff policies. *Physical attributes:* Suite of four rooms in Strong Hall with office furnishings and equipment. *Temporal characteristics:* My occupancy continued for 3 years; open for regular business weekdays 8:00 a.m. to 5:00 p.m., and for special business at any time. *Human components:* Myself, other staff members, students, secretaries. *Boundary properties:*

Open access. *Powers of human components:* The basic policies of the Department were determined by external settings: those of the University administration and the setting Department Staff Meeting. Within the constraints imposed by these settings, the chairman had complete control of the Office.

In my 19 years of academic life the extent of my administrative experience was limited to registering and advising students at Illinois and Stanford and to voting on minor issues in the College Staff Meeting at Illinois. My former colleagues at Stanford expressed anxious surprise that I would or could become an administrator. Their surprise was not justified. They did not know the strength of my commitment to certain academic and educational principles and my eagerness to have more of a hand in promoting them than hitherto; and they did not know that administration was part of the package that included Oskaloosa, the crucial component. There were grounds for their anxiety, though not the ones they probably had in mind. They would know of my deficiencies in keeping appointments, answering correspondence, arranging schedules, making and keeping to budgets, gregariousness, and so forth. But they would underestimate, I think, the power of the behavior setting Office of Department Chairman to take me in hand in these respects. However, their anxiety (and mine, too) would have been justified had they known of the probable conflict between the duties of the Office of Department Chairman and those of the research setting Field Station in Oskaloosa. I lasted 3 years as chairman.

The usual conflict between administration and research was exacerbated in this case by a geographical factor; we found it impossible to do the research in Oskaloosa, 20 miles from Lawrence, without living there and having full-time headquarters there; and the urgencies that occurred in both places could not be scheduled. However, if I had found administration congenial and rewarding, I might have remained longer as chairman. But I did not. For one thing, I did not have easy relations with my superiors. Some sort of a personal status and power problem was involved. I saw myself as being too submissive to policy directives I opposed, and thereafter I felt guilty of betraying my principles. I did not stand up to authority in the way I thought I should. This was partly a matter of my divided commitment; I did not have the time to prepare for hassles with top administrators; but there was also inability to confront superior power. Another problem for me as chairman was the discovery that persons with whom I agreed and had harmonious relations were not always in agreement and harmony among themselves. My ambition was for a unified, amicable department, and with incredible naiveté I supposed that those with whom I was congenial would be congenial inter se. There were no great conflicts within the department, but not the unity I had hoped for. An added circumstance that interfered with maintaining a department with a common point of view on psychological matters was the rapid increase in the staff to serve the great increase in university enrollment after 1947. Inevitably those added were of a variety of psychological persuasions. In my 3 years in the chairman's slot, the Department was invigorated with staff members who received wide recognition as scientific scholars in the next two decades.

These were tremendously busy years for me, with increasing conflict between the demands of the chairmanship and the research, with increasing dissatisfaction with my relations with University administrators, and with some disappointment that my goal of a small, excellent, unified group of scholars was not more completely achieved. So, my occupancy of the chairman's position in the Office of the Department of Psychology brought me both satisfactions and regrets.

Classroom teaching was not clear sailing either. I had decamped when there was administrative interference with the way I wished to function as instructor at the University of Illinois. Now, it was discouraging to me to discover that there were other, more pervasive institutional obstacles to my teaching. The Kansas University administration intruded very little in class operations, but a generally prevailing program of classroom instruction made it difficult for me to establish the kinds of programs I desired. This was my

irst experience with the fact that the settings of an institution may be so interdependent hat deviant settings cannot function. My lasses were arranged to foster students' skill n formulation of questions, finding and using he most relevant evidence, and writing re-orts on the basis of the evidence. Learning acts had no place in my classes; today's facts re obsolete tomorrow, and the current ones re always available if one knows where to ind them and how to use them. My classes ould operate best if the students had some nscheduled time: to think of interesting and nswerable questions, to search for relevant vidence, and to analyze, organize, and pre-ent the findings. But who can think, search, nalyze, and write when confronted with two uizzes a week in one class, 500 pages of eading in another, and 9 hours of laboratory ttendance in another? As so-called standards ent up and competitive grading became more evere, the students lost their freedom to act s inquirers, problem solvers, and expositors o the imposed demands of fact-, page-, and our-oriented classes.

In addition to trouble with the teaching ystem within the University, I found that lassroom settings and research settings do ot mix—that the activities required by class-oom teaching and by research are so conflict-ng as to be mutually injurious. I have ob-erved this to be true for others, too. Both erman and Lewin were excellent classroom eachers when they devoted themselves to it, ut when they were deep in research, as they sually were, their teaching declined pre-ipitately.

From the intrusions of the Illinois Dean I scaped to Stanford; from the interference of he prevailing teaching system and the con-icts with research I escaped to Oskaloosa. ortunately a Research Career Award from he National Institute of Health made this ossible.

ield Station in Oskaloosa

rogram: In the beginning, the program was to escribe the living conditions and behavior of all the hildren of the town; later, all inhabitants were in-luded. ***Physical attributes:*** Suite of offices in Oska-osa, Kansas, with office furnishings and calculators; at intervals a satellite Station was established in Leyburn, Yorkshire, England. ***Temporal characteristics:*** Operated during regular office hours, and often into the evening for particular staff members, from the fall of 1947 through the spring of 1972. ***Human components:*** Three to seven staff members, one to four graduate students, and occasional town residents. ***Boundary properties:*** Staff and graduate students selected and admitted by Station directors; they thereafter had free access; townspeople also had free access. ***Powers of human components:*** During the first 7 years, the Station was administered by the codirectors, Herbert F. Wright and me; we had power over the entire setting; when Herbert left the Station, I was in charge. Next in power were professional scientists (field workers, data analysts) who had complete control of their special operations; after them came the graduate students with power over their projects in consultation with their advisers, and finally the secretaries, who were masters of their own desks and secretarial facilities. Townspeople and other visitors had no power.

Here, at last, in the Midwest Psychological Field Station, the stream of my professional behavior entered a setting constructed to my own design: I initiated it, and its program was arranged cooperatively with Herbert Wright. Most other major settings I had inhabited had ongoing operations into which I was incorporated, with limited power to make alterations. I soon discovered, however, that in the Station I was not a free spirit but was captive of the setting I had established—a setting that embodied a past I could not escape and a future I could not control. Herbert and I had programmed the Midwest Field Station to describe the behavior and psychological habitat of the children of the town individually. With the setting underway (procedures developed and tested, staff trained, computer programs set up, citizens alerted and cooperative), it was not a simple matter when our insights and intentions changed to alter the program to one of describing extraindividual behavior within behavior settings. We had to struggle against our own creation. It makes one wonder how much of the stability of individual behavior has its source in the stability of the behavior settings people create and inhabit, a stability that is sustained by the fact that people establish new settings according to designs they carry with them from previous settings. The origins of some features we built into the

Midwest Field Station are fairly clear: The aim to describe the living conditions and behavior of all of the children originated in the Extension Classes in Illinois; concern with the naturally occurring environment was brought from Stone's Animal Laboratory and the Iowa Nursery School Laboratory; disciplined, persisting concentration on a rather narrow program of activities, the policy that "dogged does it," came aboard in the Stanford settings; the dual importance of precise data and precise theories welded together characteristics of both the Stanford and the Iowa settings; the particular theories that undergirded the program of the Midwest research came from Lewin's Offices in Iowa; the importance attached to archives of atheoretical data originated in Stone's Animal Laboratory; the first data collecting system we installed, the narrative record, dated back to the Iowa Nursery School Laboratory; the importance given to community relations was first met in Miles' Later Maturity Facility. These problems, emphases, methods, and theories with which we endowed the Field Station were imported from earlier settings. We installed the past in the present. But the inheritances were assembled in new relationships, and new elements were added, including staff members, methods, ideas, and data; the Station developed a dynamic of its own with unforeseen consequences for its inhabitants. For me these were far-reaching. In this latest stretch of the stream of my professional behavior, I entered the Field Station as a psychologist aiming to study the naturally occurring behavior and environments of the people of the town as individuals. For a long time I clung to the view that this was the way to observe and explain their everyday activities. But the Field Station finally turned me around and showed me that more than people and the stimuli that impinge upon them individually are required, that an ecobehavioral science of extraindividual behavior and its nonbehavioral context is needed. The course of this change has been presented in a number of publications (Barker, 1960, 1963a,b, 1965, 1968; Barker & Associates, 1978; Barker & Gump, 1964; Barker & Schoggen, 1973; Barker & Wright, 1951, 1955).

Other Places, Other People

I have had to omit many rewarding and pleasant reaches of my behavior stream and most of the people who shared parts of it with me and gave me tows and directions. Space is a factor here, but more important is absence of records of the early days. And there were important hidden settings (committees, administrative offices, and so forth), whose inhabitants I do not know, that gave me free time (Research Career Award: Fellowship, Center for Advanced Study in the Behavioral Sciences), research grants (U.S. Public Health Service, Society for the Aid of Crippled Children, Commonwealth Fund, Ford Foundation, Carnegie Foundation of New York, University of Kansas, Kansas University Endowment Association), honors (Kurt Lewin Award, Society for the Psychological Study of Social Issues; Research Contribution Award, American Psychological Association; G. Stanley Hall Award, Division on Developmental Psychology, American Psychological Association), and summer appointments (Columbia, Oregon, Colorado, California). I regret especially not being able to name the graduate students who studied with me at Stanford University, Clark University, and the University of Kansas, some of whom have become valued colleagues, and many of whom contributed greatly and still contribute to my intellectual development. My story would be too incomplete, however, without four prime influences on the odyssey. Louise Shedd Barker was an eager spectator, a frequent adviser, and an occasional stand-in in all the early settings. But when we discovered that the Station could not be operated from Lawrence, that it required us to live in Oskaloosa, Louise became an essential operative as chief field worker and our main line of communication with the community. She was well prepared. In her own professions she had experience as a field ecologist, first as biologist at the Stanford Marine Station and on the University campus, and then as high school "home visitor," searching out the homes of absent children and investigating the causes of their absence. Fritz Heider's ideas about media and things provided the link between

people and behavior settings that prompted me to see the latter as more than convenient areas for sampling behavior but rather as entities (things) that impose patterns upon their components, including their human inhabitants (media). It was this insight that raised behavior settings for me from a technological convenience to the basic unit of an ecobehavioral science. Herbert F. Wright was co-equal developer of the Field Station's program during its first years, making unique contributions to the study of individual behavior; and Paul V. Gump was equally important in the latter years by bringing the Station's ideas and methods to bear on school and community operation.

Conclusion

I began this trip with the desire to benefit humanity. I have not, myself, been able to satisfy this desire, for I have found that, as with teaching, the time and skills required to make and disseminate applications have so conflicted with those required by the research as to make the former impossible for me. So the zeal and success of a small number of former staff members, students, and others to bring our methods and findings to earth in connection with hospitals, schools, architecture, town planning, child development, and even the movement "small is beautiful" have given me keen satisfaction. I began the journey, too, with reservations about my ability to make it in the scientific world. When I report that the self-doubt has not been dispelled, the response may well be: How greedy can he be? What does he want in brownie points? The answer: The stream of my professional life has skirted the areas of psychology that are currently richly cultivated and harvested, and in fact, it has finally landed me outside the turf of the psychology tribe. Being something of a maverick has its rewards from those (and there are many) who value what they hope will prove to be worthwhile innovations. The innovator hopes so, too, but in the meantime he is at a disadvantage vis-à-vis his mainstream associates, since he cannot keep up with them in the main channel. So, how can he be sure where he stands?

Roger G. Barker and Behavior Settings: A Commentary

Phil Schoggen
Cornell University

These comments on the preceding paper by Roger G. Barker suggest that it documents and illustrates Barker's approach to science, his lifelong concern with environment–behavior relations, the major influences that have shaped his thought, and the utility of the behavior setting concept.

Barker's paper impresses me as a remarkably accurate, concise, and revealing reflection of his lifelong approach to science in general and to the study of the relations between molar behavior and its environment in particular. It sketches and illustrates in a fascinating way the development of his most significant conceptual contribution, the behavior setting, from its earliest precursors in Calvin Stone's animal laboratory to its present status in the broader domain that he now refers to as "an ecobehavioral science of extraindividual behavior and its nonbehavioral context." And he does it with the candor and wit that his associates will recognize as so characteristic of Barker. Of course, a good understanding of Barker's work requires study of his several books and papers, but I know of no single paper that is more truly indicative of Barker's thinking than this one. I have tried below to identify some of the main reasons why I have this impression.

This paper, above all, documents well a way of going about scientific work that both Barker and his principal mentor, Kurt Lewin, had in common, namely a spontaneous and omnipresent genius for finding in the mundane experiences of one's own everyday activities inspiration for the development of new concepts or practical tests of hypothetical relationships. For example, Lewin used his World War I battlefield experiences to develop his concept of the psychological environment (Lewin, 1917). His astute observation of a coffeehouse waiter's impressive memory for hours of charges and sudden forgetfulness once the bill was paid served as a basis for his conception of psychological tension systems (Marrow, 1969). Similarly, Barker's experiences on train trips through the countryside of central Illinois spawned his subsequent preoccupation with studies of "the nature of the situations that actually confront children in their daily lives and how they react to them" (Barker & Associates, 1978). Where others saw only pleasant countryside and small midwestern towns, Barker saw a major challenge to scientific psychology. His efforts to cope with illness and physical disability shaped his thinking about the relation between the psychological and the nonpsychological environments. Like Lewin also, Barker encouraged his students and colleagues to use their own direct experiences to further their understanding of fundamental psychological processes. As a graduate student research assistant and resident staff member on the Midwest project in its early days, I regularly attended church and sang tenor in the church choir. On one of our many trips by car between Lawrence and Oskaloosa, I remember expressing puzzled amazement at the faithfulness of the other parishioners—I couldn't understand why they so dependably braved the rigors of Kansas winters and suffered through Sunday after Sunday in the sweltering heat of summer to be present for the morning worship service. In his quiet, hesitant, almost apologetic way, Roger said,

"Well, I don't know. But, Phil, why do *you* go?"

This paper also documents another important feature of Barker's career in that it shows both his early concern with the problem of environment–behavior relations (he was writing about ecological problems many years before any other psychologist except Lewin and Brunswik) and the impressive singleness of purpose with which he has dedicated himself to this concern, forsaking all others. With his long-time friend and colleague Herbert F. Wright, Barker wrote in 1949 on what they then called *psychological ecology* (Barker & Wright, 1949). This was followed by their major report on the Midwest project (1955), Barker's seminal theoretical paper in the Nebraska Symposium on Motivation (Barker, 1960), his now classical *Ecological Psychology* (Barker, 1968), several other books and papers alone and with colleagues, and most recently, a new work that presents his current thinking about ecobehavioral science, which goes well beyond ecological psychology (Barker & Associates, 1978).

Dedication to his early learning at Stanford that "dogged does it" is apparent also in the fact that, with the single exception of the 1953 revision of his Social Science Research Council monograph on the social psychology of physique and disability (Barker, B. Wright, Meyerson, & Gonick, 1953), every one of Barker's seven books and 22 papers published since 1949 is devoted to the ecology of behavior.

Barker (1963) has credited Kurt Lewin and Egon Brunswik as the intellectual forebears of his work on the ecology of behavior. In the present paper, he also traces his concerns for understanding environmental influences on behavior to some rather surprising beginnings. Barker's thinking reflects still other important influences.

The work of social anthropologists such as Margaret Mead, Clyde Kluckhohn, and Ruth Benedict figured prominently in the thinking of Barker and Herbert Wright in the early days of the Midwest Field Station research. I recall many discussions of the project staff during which great admiration was expressed for the pioneering efforts of the social-anthropologists to study behavior in natural situations. Although Barker and H. Wright wanted to study child behavior and development in ordinary American as opposed to primitive cultures, and although they tried to develop observational and recording methods more systematic than the traditional field notes of the social anthropologists, it is clear that Barker and H. Wright built heavily upon the foundation laid by these workers.

Sociology and particularly human ecology also provided important influences. I remember well my delight in finding that my oral examination for the master's degree surprisingly turned into an interesting debate among Roger Barker, Herbert Wright, and Martin Scheerer as to whether the classical study of mental disorders in different areas of Chicago by sociologists Faris and Dunham (1939) could be considered a study in psychological ecology. This discussion showed clearly that the thinking of Barker and H. Wright was strongly influenced by the work of sociologists. This was evident also from their familiarity with and appreciation of other related sociological literature, for example, Dollard's *Caste and Class in a Southern Town,* the Lynds' *Middletown in Transition,* and Hollingshead's *Elmtown's Youth.*

A less conspicuous but still important influence on Barker's thinking came from the field of biology, which provided him with extremely useful models. Although it was clear to me that Barker had done a considerable amount of reading in biology on his own, I think Louise Shedd Barker's formal training in biology and her central involvement in Roger Barker's thinking throughout his career greatly enhanced the value of concepts, principles, and research strategies from biology in the development of his own ecological approach.

Certainly Barker's concept of ecology came directly from its use in plant and animal ecology. Webster's unabridged dictionary definition suits equally well Barker's use of the term and that of biological ecology, "the totality or pattern of relations between organisms and their environment."

In his early attempts to get some project

staff members to understand the mutual interdependence of behavior and its immediate context, Barker spoke of the well-worn footpath that cut diagonally across a familiar vacant lot near the high school in Oskaloosa. At some earlier time, the path did not exist, and the first persons to cross the lot diagonally shaped that part of the environment in line with their need to reduce the amount of required walking. Yet the path that they created was not completely straight but curved and bent around clumps of bushes, mounds, and depressions. Once established, however, that path shaped the behavior of countless pedestrians, nearly all of whom now follow its curves and bends as faithfully as a train on steel rails.

Eugene P. Odum in *Fundamentals of Ecology* (1971) expresses the same thought in the context of his discussion of the ecology of fresh water ponds: "Not only is the pond a place where plants and animals live, but plants and animals make the pond what it is" (p. 12).

Finally, it is appropriate that Barker chose to write in terms of behavior settings central in his professional career, because the concept of behavior settings will, I believe, turn out to be his most important and enduring contribution. Its potential significance for behavioral science is only beginning to be recognized (e.g., Moos, 1976; Wicker, 1979). To the best of my knowledge, it is the only concept in the behavioral sciences that combines both the ecological environment and behavior in a single unit of empirical analysis. The behavior setting concept derives from and reflects Barker's concept of the environment (Barker, 1963). This concept marks Barker's originality and most clearly distinguishes his position from those of Brunswik and Lewin. Whereas for them and for psychologists generally (e.g., Leeper, 1963), the ecological environment is unstable, characterized by only statistical regularities, and related to behavior only in terms of probabilities, Barker argues and provides impressive empirical evidence that there is order and organization in the preperceptual environment and that its relation to behavior is neither random nor merely probabilistic. Although the laws that govern the phenomena of the nonpsychological environment are different from and incommensurate with the laws that govern individual behavior, Barker and his associates have demonstrated in their work with behavior settings that despite this conceptual incommensurability, our understanding of molar behavior can be improved through systematic studies of its relations with the immediate environmental contexts. Behavior settings and the molar behavior of their inhabitants are mutually, causally related. Barker's review of important behavior settings in his own professional career provides further testimony to this important discovery.

The Identification of Persons as Supersets and Subsets in Free-Response Personality Descriptions

Michael A. Gara and Seymour Rosenberg
Rutgers—The State University

Using a free-response format, 14 subjects each described 36 target persons. A set-theoretical model was proposed for representing the perceived similarities and differences among the persons described. Using this model, four types of targets were identified for each subject's protocol: supersets, subsets, disliked contrasts, and miscellaneous. Supersets are persons whose perceived characteristics subsume those of many of the other persons described. Subsets are persons described with only a limited portion of the characteristics attributed to the supersets. Disliked contrasts are those disliked persons who were described with a set of terms almost completely different from those used to describe the other targets. Miscellaneous targets are target persons who could not be identified as supersets, subsets, or disliked contrasts. As predicted, the supersets were persons who were perceived by the subjects to be very significant in their lives. Disliked contrasts were persons whom the subjects perceived as least significant; subsets and miscellaneous targets could not be distinguished from one another in this regard. It is suggested that supersets provide the perceptual categories for the construing of persons, and the correspondence of this idea with other extant psychological ideas, such as transference, is discussed.

We are often in the process of comparing people with each other. Our conversations are punctuated with statements such as "Those two sisters could hardly be more different" and "John and Bill are as alike as two peas in a pod." It does not seem unusual, then, that the perceived similarities and differences among the people known by an individual have occupied the serious attention of social psychologists in the area of person perception. These perceived relationships have been examined in a number of studies (Cronbach, 1958; Jackson, Messick, & Solley, 1957; Jones & Young, 1972; Messick, 1961; Rosenberg, 1977).

As part of the analyses of these perceived relationships, a measure of the psychological proximity of each person in a subject's life to each other person was defined in each of the above studies. The measures chosen all satisfied the symmetry assumption. That is, the similarity of Mary to John is defined as equal to the similarity of John to Mary.

A considerable number of theoretical and empirical arguments make the assumption of symmetry questionable. Within the field of person perception, the possibility of asymmetric relationships among personality descriptors has been raised several times at the theoretical level (Hays, 1958; Jackson, 1962; Rosenberg & Sedlak, 1972). At the empirical level, there is a study by Warr and Knapper (1968) in which subjects made inferences on an adjective checklist about a target person who had been initially described by the investigators with six different cue traits. The subject was asked two questions for any given pair of traits: If this person is cynical, how likely is he to be precise. If this person is precise, how likely is he to be cynical? The

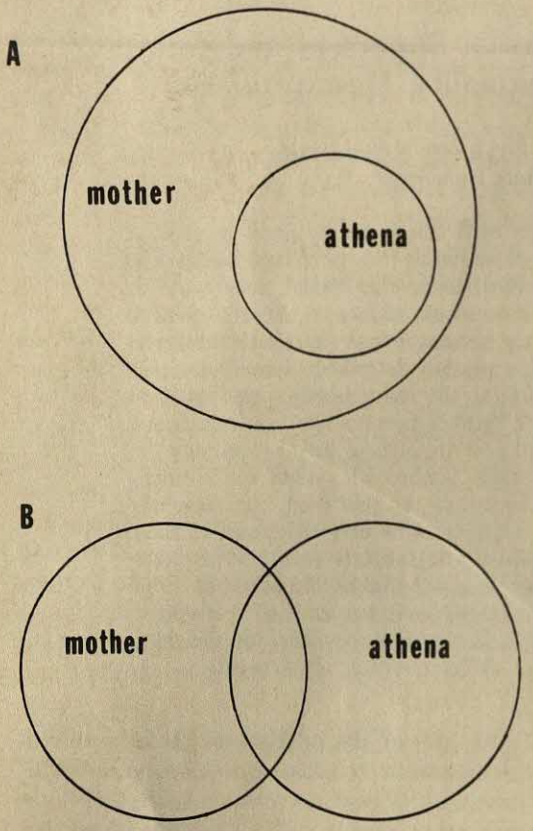

Figure 1. A: Hypothetical superset relationship. B: Hypothetical symmetric relationship.

results indicate marked asymmetries: Being *cynical* implied being *precise,* but being *precise* did not imply being *cynical.*

The notion of asymmetry has also received attention outside the immediate sphere of person perception. Working in the tradition of personal construct theory, which shares methodological and substantive concerns with person perception research, Hinkle (1965) developed a technique (IMPGRID) for assessing the one-way implications between constructs. Furthermore, investigators have found asymmetric similarity judgments with objects such as countries and geometric figures, (Tversky & Gati, 1977), auditory signals (Wish, 1967), and colors, line orientations, and numbers (Rosch, 1975).

In the present study, a set-theoretical model of person perception is used to depict the target persons described by subjects. This model permits asymmetries in the description of the targets to be reflected in the set-theoretical relation of targets to each other. The most extreme type of asymmetry is depicted in Panel A of Figure 1: Athena is a proper subset of Mother. The fact that Athena has an attribute implies that Mother has it as well; however, the converse is not true. Hays (1958) proposed a set-theoretical model for the relationships among personality descriptors, but it received little subsequent attention.

In this study, the set-theoretical relation between targets is measured by a special implication phi (here denoted ϕ_I) that was proposed by Francis (1961). Unlike the standard phi coefficient for the correlation between two dichotomous measures, there are two ϕ_Is for any two target persons, A and B, one for A → B and one for B → A. It is the inequality of these two phis that reflects the degree and direction of asymmetry. When there is a symmetric relationship between targets such as that depicted in Panel B of Figure 1, the two phis will be equal.

The application of a set-theoretical model to the target persons that an individual describes has a special appeal. Some targets (dubbed *supersets*) may bear the superset relation that Mother bears with Athena in Panel A of Figure 1 (although it may not be perfect) to many other target persons described. A group of other targets (dubbed *subsets*) bear relationships akin to that which Athena bears to Mother in the same figure.

It seems reasonable that supersets are persons in an individual's life who provide the perceptual categories for the construing of other persons. The underlying notion is that supersets are persons with whom the individual has interacted in many different types of situations. A good deal is thus known about these persons in terms of personality characteristics, and a portion of these may consequently be assigned to persons known less well. In fact, the personality characteristics referred to by the personality terms that an individual uses to describe people were probably first observed in these supersets.

Consequently, we should find that these same supersets are known more intimately by

the subject than are subsets and any other type of target we identify. In addition, supersets are probably perceived as more complex than other targets, and the affect that is displayed in their presence is more ambivalent (multivalent) than that displayed in the presence of other targets. Further interaction with nonsupersets may result in a significant impression change, whereas the overall impression with regard to supersets should be already well formed and slow to change. In sum, supersets are the most significant people in an individual's life.

To test these ideas we obtained a data base independent of the one we used to identify supersets and subsets. This consisted of ratings of the targets on several properties that we thought would differentiate the targets in terms of how *significant they were in a subject's life*. Then the question was asked: Are supersets the significant persons in the subject's life?

Method

Subjects

Ten female and four male undergraduates enrolled in a psychology course at Livingston College served as subjects. Each subject was paid $36 for participating in the study, which involved approximately 10–15 hours of his or her time. Subjects were told in advance that they would be paid only upon the completion of their work, that incomplete work would receive no payment.

Procedure

The first data that were obtained consisted of each subject's descriptions of a sample of people that he or she knew. This data base was used to identify the supersets as well as the other types of target persons for each subject.

In obtaining these data for each subject, the free-response methods developed by Rosenberg (1977) were followed exactly, except for the way target people were selected. For that purpose the subjects were provided with a list of 36 role descriptions (Table 1). A subject was instructed to read each role description and then list a person in his/her life who seemed to fit that particular description best. Thus, subjects generated their own lists of 36 target persons to describe.

The free-response method for obtaining descriptions of these targets required that the subject generate his/her own descriptive vocabulary. Each subject generated two different kinds of vocabularies: *traits* that the subject perceived as descriptive of the various target people and *feelings* that were elicited in the subject by these target people. The subject was asked to formulate his/her trait perceptions and feelings in the form of discrete units, but not necessarily single words. The subject cumulated a trait and feeling list as he/she described the target persons —that is, when he/she used a trait or elicited feeling to describe one person, he/she was asked to judge the presence of that trait or elicited feeling for all the other target people.

Before systematically describing any of the people on his/her list, each subject prepared two "starter lists," one of traits and one of feelings. To obtain these lists, the subject was instructed to write down on a provided questionnaire the first five traits char-

0	*c*	*d*

Note. 0 = target does not possess attribute; 1 or 2 = target does possess attribute. *a*, *b*, *c*, *d* = number of times a given combination occurs in description of target person.

acteristic of, and first five feelings elicited by, Targets 1, 7, 12, 14, 18, 21, 23, 26, 30, 32, 34, and 35. The starter lists served not only to reduce biases in content that might be associated with the first few people on the list but also to help the subject get started with the description task. Once collected, the two starter lists were each randomized for each subject, and the description task began. The descriptions were collected on a computer terminal tied to the Rutgers time-sharing system. Each subject entered his/her list of 36 target persons and the two starter lists, one of traits and one of feelings. A computer program (Livingston & Kingsley, 1976) was used to (a) present the subject with his or her list of target persons one at a time; (b) present for each target person all descriptors (traits or feelings) the subject had entered; (c) record the subject's judgment (0, 1, 2) of each target person on each descriptor; (d) record any new trait (or feeling) term that the subject wished to add to his or her vocabulary of terms; (e) re-present for judgment the persons already described, when a new trait (or feeling term) was added.

Subjects were instructed to make the trait and feeling judgment on a 3-point scale. For traits, these were:

0 = the trait is not descriptive of the person, but does not necessarily mean that the person possesses the opposite trait (in order to indicate that the person possesses the opposite trait, the subject was instructed to add the opposite as a separate trait term).

1 = the person possesses the trait to a noticeable degree but need not describe the way the person is all the time.

2 = the person posseses the trait to an extreme degree but need not describe the way the person is all the time.

A similar scale, appropriately worded, was used for the feelings.

0 = the person does not make (or has not made) you feel this way.

1 = the person makes (or has made) you feel this way to a noticeable degree.

2 = the person makes (or has made) you feel this way to an extreme degree but need not make you feel this way all the time.

During this entire process of describing the 36 target persons, the trait and feeling vocabularies were kept separate: A subject systematically alternated between trait and feeling descriptions according to a fixed schedule. The subject started with trait descriptions for the first 5 people on his/her list, followed by feeling descriptions for the first 10 people on the list. The subject switched back to trait descriptions and alternated them with feeling descriptions, such that after persons n through $n + 9$ were described by traits, persons $n + 5$ through $n + 14$ were described by feelings.

When the description tasks were all completed, the trait and feeling vocabularies were combined for each subject. Thus the computer contained 0, 1, and 2 entries in a $36 \times n$ descriptor matrix for each subject.

Identification of Supersets and Subsets in a Subjects Protocol

Suppose we represent all possibilities of perceived trait and feeling occurrence in Person A with respect to Person B, using a 2×2 table (Table 2), where 0 represents the rating that the target person (A or B) does not possess an attribute, and 1 or 2 represents the rating that the person does. The cell entries *a*, *b*, *c*, and *d* each represent the number of times that a given combination occurs in the actual description of these two persons.

The relationship expressed with the Venn diagram in Panel A of Figure 1 depicts Mother as a proper subset of the goddess Athena. Let Mother be Person A and Athena be Person B in Table 2. As seen in Panel A of Figure 1, whatever attributes Athena possesses, Mother does also. In other words, *c* must equal zero. For the general case, whenever we can marshall evidence that the *c* cell is indeed equal to zero, we can state that Person B is a proper subset of Person A. Situations where *c* is small but not equal to zero can be placed on a continuum of what Francis (1961) calls "weak implication" and he demonstrates that a ϕ_I coefficient (range from -1 to 1) can be calculated, where

$$\phi_I = \frac{ad - bc}{(a + c)(c + d)}. \quad (1)$$

A high positive value indicates the degree to which Person B's characteristics are a subset of Person A's. A high negative value indicates that Person B implies the opposite of Person A.

For the weak implication case, ϕ_I's were calculated for each subject for all pairs of targets described, yielding a 36×36 matrix of ϕ_I's for each subject. Each entry indicates the extent to which the characteristics of the target in column j are a subset of the characteristics of the target in row i. By definition, the diagonal entries are 1.

To simplify examination of this matrix, the rows and columns were permuted separately to bring into proximity rows or columns with a similar pattern of

ns. This permutation was done according to a hierarchical clustering of the rows of the matrix and then separately of the columns, using as input a profile distance

$$\delta_{ij} = \sum_{k=1}^{36} (\phi_{1,k} - \phi_{1,k})^2 \qquad (2)$$

alculated separately for rows (where k refers to olumns) and columns (where k now refers to rows). his simple type of two-way clustering is described some detail in Rosenberg (1977).

Figure 2 illustrates a sample protocol from one ubject following two-way clustering. All target perons numbers in Figure 2 correspond to the numbers f the role figures in Table 1. In this example, the ow labeled 1 (which is Mother) illustrates the egree ($\phi_1 \times 10$) to which the characteristics of each rget designated in the columns—6, 11, 24, and so rth—are subsets of the characteristics attributed Mother. A minus sign indicates that the ϕ_1 is egative, whereas an asterisk indicates that $\phi_1 = 1.0$.

Distinct clusters of targets in Figure 2 are sepated by horizontal lines for the row-wise clustering nd vertical lines for the column-wise clustering. he following guidelines were used to group the rgets (row-wise and column-wise) for each subct. We chose the level of the hierarchical tree proced by the clustering program that separated the 6 targets into 7 clusters. If there was a comparaively large cluster (in terms of number of targets ntained) remaining at this level of the tree, a gher level of the tree was chosen to break up this uster. However, in no case were more than 11 clusrs chosen.

After the clustering of the targets had been fixed this way, targets were classified as supersets, subts, disliked contrasts, or miscellaneous for each ubject, as shown in Figure 2. (Miscellaneous targets re not labeled in Figure 2.)

Note that target persons in the same cluster share very similar pattern of ϕ_1s. To indicate the genral size of the ϕ_1s within a cluster, the sum of all quared ϕ_1s within a cluster is averaged by the numer of targets within that cluster, and this number shown for each row and column cluster in Figure . To be classified as a superset, it is necessary, but ot sufficient, that a target be included in the luster(s) of targets with a pattern of high ϕ_1s *row-wise*. Similarly, to be classified as a subset, it is ecessary, but not sufficient, that a target be inluded in the cluster(s) of targets with a pattern of igh ϕ_1s *column-wise*.

The reason that the above conditions are necessary ut not sufficient for classifying targets as supersets r subsets is that a given target could occur in both lusters described above, if that target was charcterized by a pattern of high ϕ_1s, both *row-wise* nd *column-wise*. That target would bear an overall *ymmetric* relation, not a superset or subset relation. uch targets rarely occur. In a total of 504 targets 14 subjects × 36 targets per subject) we classified 1 targets as supersets, 71 as subsets, and only 23 as symmetrical. Moreover, the latter were found in only 7 of 14 subjects.

In every case, a cluster(s) of target persons emerges with negative phis in relation to supersets and subsets. This category was dubbed "disliked contrasts" because without exception, only the disliked role figures in Table 1 emerge in this category.

Targets not identified as supersets, subsets, or disliked contrasts are grouped into a miscellaneous category. Included in this category are the symmetric targets, as defined above.

Property Ratings

The other data that were obtained from each subject after he/she had completed the person description task were ratings of each of his/her target people on the properties listed in Table 3. These properties were constructed to assess the significance of each of the target persons in the subject's life. The property ratings were then used to test the idea that supersets, which had been identified in the free-response protocols, were significant people.

Results

In order to relate the interpersonal significance of a target person as assessed by the property ratings with the type of target as identified by the ϕ_1s, a multivariate analysis of variance (MANOVA) was performed on the property ratings. The target type effect (which has four levels: supersets, subsets, disliked contrasts, and miscellaneous) was tested against the variance–covariance matrix for the Target Type × Subject interaction,[1]

[1] Using a test proposed by Huynh and Feldt (1970), we found that certain assumptions were not met that were requisite to the validity of this particular test of the main effect when repeated measures are involved. To ensure the validity of the reported findings, alternative procedures of analysis were pursued. These involved the calculation of three orthogonal contrasts among each subject's four target type means for each property and testing these contrasts for flatness using a Hotelling T^2 and Bonferroni adjusted significance levels. There were significant differences among the four target type means for every property except Complexity and Feeling Ambivalence. Specific contrasts among the target type means for each property were also tested (essentially a single sample t test of the hypothesis that the population value of the contrast is zero) using Bonferroni adjusted critical values (Harris, Note 1). The profile of results using MANOVA is essentially replicated by these procedures, thus only the MANOVA is reported. A summary of these alternative analyses is available from the author upon request. We thank John Miller for his assistance with these analyses.

Table 3
List of Properties Used to Rate Targets

Label	Question	7-point bipolar scale
Self-Disclosure	1. How much do you discuss personal problems?	not at all–a lot
Concern	2. How concerned are you about whether this person thinks well of you?	not at all concerned–very concerned
Self-Expression	3. How far do you express feelings of love, approval, or admiration for this person?	try to conceal–express freely
Range of Interaction	4. In how many different types of situations have you interacted with this person?	limited–many
Closeness	5. How close are you to this person presently?	little–very
Complexity	6. How could you characterize the complexity of this person?	simple–complex
Feeling Ambivalence	7. How conflicted or ambivalent are your feelings about this person?	little–very
Impression Stability	8. If you were to interact with this person in many more types of situations than you do now, what do you expect would happen to your impression of this person?	it would change a great deal from what it is now–it would not change much from what it is now

riminant functions that distinguish among he groups. Harris (1976) argued that Wilks's ambda, although providing a valid test for n overall effect, cannot be used as a test or the significance of any particular discrim-nant function, including the first. He recom-nended comparing the characteristic roots ssociated with each discriminant function to he critical value of the greatest-character-stic-root distribution. This procedure was ollowed, using the *s*-parameter specifications uggested by Harris for testing each root and he same *m* and *n* parameters as for the over-ll test. (See Morrison, 1976, p. 189.) The est statistic .420 was extracted for the first iscriminant function and was statistically ignificant ($p < .01$). The second and third iscriminant functions were not found to be ignificant.

The first discriminant function associated with the target type effect accounts for almost 85% of the variation in the property ratings and is the direction in these data that most distinguishes the four target types. To clarify this discrimination, a Duncan multiple com-parison procedure was performed on the multivariate means, which are obtained, one for each target type, by multiplying the prop-erty means collapsed across subjects by the first discriminant function. This procedure revealed that the supersets scored highest ($p < .001$) on the linear combination of the properties yielded by the first discriminant function. There were no significant differences between subsets and miscellaneous targets, and the disliked contrasts scored lowest.

The actual discriminant function coefficients and the loadings of each of the eight properties on this function are presented in Table 4. The loadings are the correlations of each property with the discriminant function and tell us how well we could estimate the discriminant function with a property if only we had that property at hand.

With respect to the discriminant function

Table 4
Coefficients and Property Loadings Associated With Target Type Effect for the First Discriminant Function

Property	Coefficient	Loading
Self-Disclosure	−.000002	.59
Concern	.020061	.94
Self-Expression	.008741	.75
Range of Interaction	−.000437	.45
Closeness	.006339	.72
Complexity	−.002833	.01
Feeling Ambivalence	.003891	−.09
Impression Stability	−.003147	.23

coefficients, the target types are largely distinguished by their ratings on the question: How concerned are you about whether this person thinks well of you? The subjects were very concerned about the opinions of supersets and least concerned about the opinions of disliked contrasts. They did not distinguish subsets and miscellaneous targets in this regard.

The profile of loadings in Table 4 presents a similar picture. Though Self-Disclosure, Self-Expression, Range of Interaction, and Closeness do a fairly good job of predicting the discriminant function that optimally distinguishes the target types, Concern does the best job. These properties are all highly intercorrelated, as we assumed they would be; they were designed to assess the significance of a target in a subject's life, albeit in different ways. There is some evidence that the impressions of supersets are stable relative to the other targets. (Impression Stability has a loading of .23 on the first discriminant function.) There is no evidence that impressions of supersets are perceived as more complex. Further, subjects did not perceive their feelings as especially ambivalent for any one type of target.

In general, the idea that supersets are significant people seems well supported. On the other hand, we were not able to distinguish subsets from targets classified as miscellaneous. This is not to say that there are not important differences here but only that the properties we happened to construct failed to capture them. Further investigation is needed to distinguish these target persons.

Discussion

In this study, target persons were described in a free-response manner by subjects. Four categories were used in the classification of targets. To recapitulate, supersets (subsets) are target persons who characteristically bear superset (subset) relations to other targets, although these set relationships may not be perfect. Disliked contrasts are characterized by disjunctive logical relationships with other targets. Targets not identified as supersets, subsets, or disliked contrasts were grouped into a miscellaneous category.

The fact that these four kinds of targets are structurally distinct does not guarantee that they will be psychologically distinct. To determine the psychological distinctiveness among these target types, independently measured ratings of the targets were obtained. In terms of the eight rated properties that were used to determine the perceived significance of each target person in the life of the subject, supersets were found to be the most significant people, as predicted, and disliked contrasts were distinguished as the least significant people. Subsets and miscellaneous targets could not be distinguished from one another.

The remainder of the discussion focuses on supersets and addresses two questions: What are supersets? Who are supersets?

What Are Supersets?

This question has already been answered, in terms of the logical relation these targets share as the characteristic way in which they relate to most other targets. To elaborate, supersets receive ascriptions from almost every content category in a subject's person descriptions. A *content category* refers to a group of descriptors (traits and feelings) that are used in a similar way by the subject in describing persons, probably because these descriptors roughly refer to some common quality detected in certain persons and/or some common quality detected (felt) in the self when certain persons are present. The use of hierarchical clustering with the free-response person description protocols is one of the methods for determining a subject's content categories (e.g., Rosenberg, 1977). Nonsupersets—especially subsets—are often described with many of the terms in one content category (or more) and few of the terms in other content categories (Gara, Note 2).

What might these structural properties of the subjects' persons descriptions say about the *process* of person perception? A statement about process is suggested from the structure of these protocols, although no data about process were directly obtained in this study.

Supersets, that is, significant persons in one's life, provide the perceptual (content) categories for the perception of other persons. This idea is certainly not new. It is involved, though stated differently, in many extant psychologies of the person (e.g., Freud, 1940/1949; Kelly, 1955; Sullivan, 1953).

Freud's concept of transference will be discussed briefly as an illustration of this idea that significant persons provide the perceptual categories for the perception of other persons. Transference refers to the situation in psychotherapy where the therapist is seen as a partial replication of a significant person in the patient's life, and the patient acts and reacts with the therapist on that basis. In other words, the therapist is a subset of a significant other. Applied to the broader context of person perception in general, rather than therapist perception in particular, transference simply refers to the experience of persons as subsets of significant others. It is interesting to note here that two of the roles that loom large in classical accounts of transference—the self (*Me Now*) and mother—are each found to be supersets in 8 of 14 cases.

Who Are Supersets?

Although more than 50% of the subjects had Mother and/or Me Now as supersets, it would be misleading to think that in terms of the role descriptions presented in Table 1, supersets only cover a small range, such as parental figures. What is true is that supersets are never mythical, public, or disliked role figures. Furthermore, in a preliminary analysis (Gara, 1978) it was found that one group of subjects had only parental figures as supersets, whereas, in another group, supersets appeared to be mostly nonparental and contemporary figures such as lovers and friends. Another group of subjects seemed to fall between these two extremes with regard to the supersets identified in the protocols.

Regardless of these differences in the role relationship of the supersets to the subjects, supersets were universally found to be very significant persons in the subject's life. What is especially striking is that the ratings of Concern best discriminated supersets from other targets. Subjects are very concerned that the supersets think well of them.

What is the nature of this concern? The answer depends on how the subject interpreted the question. Subjects' ratings on other properties show that they feel close to supersets, that they discuss personal problems with supersets, and that they freely express their feelings with supersets. It could be that subjects' ratings of supersets on Concern reflect their desire that these important people in their lives accept them totally, regardless of shortcomings. In other words, the question could have been interpreted as the desire for unconditional positive regard (Rogers, 1959) from supersets.

On the other hand, there is the possibility that some or all subjects interpreted the question as an assessment of how positive they wanted to appear to a target. In this case, when the subjects report, as they do, that they express themselves freely with supersets, the spontaneity of the expression is limited by their concern that they will appear positive. That is, subjects *monitor* themselves in the presence of supersets. Regardless of what role the superset bears with the subject, even if the superset is the self-concept itself, there is always at least one phenomenological representation of a person that, in effect, monitors the individual. The notion that the self-concept itself can be a monitor is not new: "Most of the ways of behaving which are adopted by the organism are those which are consistent with the concept of the self" (Rogers, 1951, p. 507). The notion of "monitoring" per se is involved in the psychoanalytic concept of introjection of the significant other, which results in the formation of the superego. Elaboration of these notions can be found in object relations theory (Fairbairn, 1954).

Future investigations of the set-theoretical representation of target persons in person perception need to be directed at the unraveling of the subjective meaning(s) of Concern vis-à-vis supersets and the investigation of the possibility that supersets are monitors. It would also be important to determine if a subject's general psychological adjust-

ment and living problems can be differentially affected depending on the role relationship he/she bears with his/her perceived monitor. That is, is it better in terms of general adjustment to have a parental figure or a contemporary figure as a superset/monitor? Are there any people with mythical/public figures as supersets (none in this study), and if so, what are the consequences? We should also not exclude the possibility that all representations of significant others are, in a sense, mythical, and the monitoring function per se that those representations serve is what is problematic in human experience.

Internalization Versus Identification in the Laboratory: A Causal Analysis of Attitude Change

Daniel Romer
University of Illinois at Chicago Circle

Two possible mediators of attitude change, internalization and identification, were investigated in a laboratory setting. Internalization was assumed to underlie change when respondents are attracted to others who hold the same opinion *and* can argue in favor of their attitude position; identification was assumed to mediate change when respondents are attracted to similar others but cannot necessarily support their position. A causal analysis based on these assumptions confirmed the independent existence of internalization and identification as mediators of attitude change. The analysis suggested that internalization involves more valid change than identification does and that attraction toward similar others is affected by both internalization and identification. These conclusions are supported in terms of both individual and treatment variation. The results suggest that attraction toward similar others does not necessarily reflect true attitude change but that valid change can be detected even in laboratory settings.

Distinguishing true attitude change from mere response change is a critical issue in the study of persuasion. Hendrick and Seyfried (1974) approached this problem by assuming that genuine attitude change would be reflected by increased attraction to others who hold the same opinion (Byrne, 1971). There are several objections to this approach, however. First, as Wells (1976) noted, demand characteristics and evaluation apprehension may just as easily affect the measurement of attraction as the measurement of attitude change. Thus, both attitude change and attraction could be disingenuous. Second, it is possible for attraction to be genuine and yet not reflect true attitude change. For example, we may identify (Kelman, 1961) with others who agree with a message without having fully accepted (internalized) the message ourselves. Third, more direct evidence of the persuasive impact of a message should be obtained before labeling its effects as valid. For example, evidence that the message has been internalized should be evaluated.

To overcome these objections, the present research employed a causal modeling approach based on Kelman's (1961) three-process model. This research was conducted to demonstrate (a) that identification and internalization are independent processes with separate determinants and separate consequences; (b) that, as Kelman has theorized, internalization is a more central response to persuasion than identification is and (c) that attraction toward similar others is a function of both identification and internalization. In addition, the research was planned to encompass both treatment and individual variation in response to a persuasive message, thereby providing a sensitive test of the similarity–attraction hypothesis (cf. Hendrick & Bukoff, 1976).

The Causal Model

Causal modeling has its roots in the biometric work of Wright (1921) and was developed to uncover causal mediators in cor-

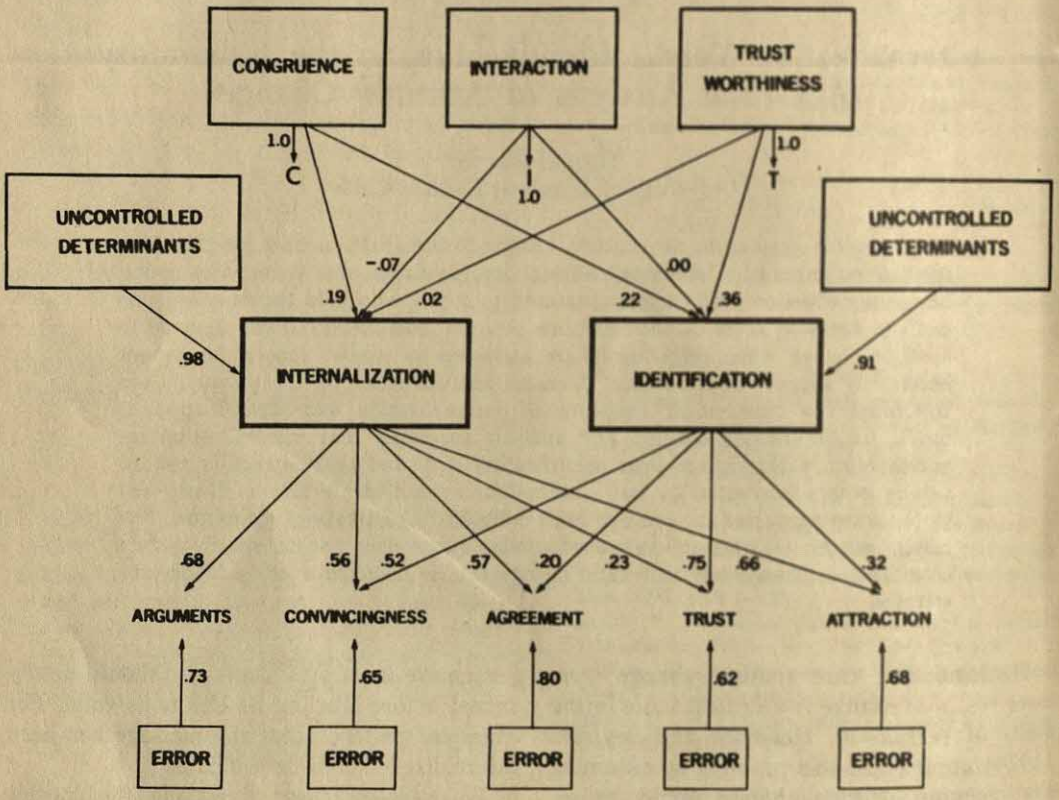

Figure 1. The causal model with observed values for causal paths.

relational research. More recent developments (Goldberger & Duncan, 1973) have extended the method to latent variables and multiple indicators. An important advance in these methods is Jöreskog's (1969; 1973) application of maximum likelihood methods to the analysis of causal models. Jöreskog's method involves the specification of a causal model assumed to underlie a data set and the confirmation of the model with maximum-likelihood factor analysis (cf. Kenny, 1976).

Although causal analysis was originally developed for nonexperimental research, it is also useful for separating latent mediating effects in experimental designs (Alwin & Tessler, 1974; Costner, 1971). In the case of attitude research, agreement with a persuasive message may be mediated by several processes. According to Kelman, the most central (and valid) change occurs when the attitude has been internalized by the recipient. It is possible, however, for change to occur as a result of identifying with the communicator or others who hold the same position. Such change reflects attraction toward others that is based on motives other than the true acceptance of the position.[1]

A causal model representing Kelman's theory as it applies to the present research is shown in Figure 1. Causal links (arrows) between variables represent the relationships that are hypothesized by the present theoretical approach (the coefficients are discussed in the results). Each observed independent and dependent variable is shown to be affected by one or more latent variables or factors (enclosed in boxes). In the model, internalization and identification are assumed to be independent processes that underlie various attitude measures (described below). In addition, the model suggests that experimental

[1] Kelman also hypothesizes the existence of a third process (compliance); however, this mediator is not the focus of the present research.

independent variables may affect one or both of the mediators at the same time. According to the model, it is quite possible that effects of internalization and identification are confounded in ordinary experimental research. The use of causal analysis, however, permits the separation of these mediating processes. In order to employ a causal analysis, it was necessary to manipulate and to measure the mediators in such a way that their causal effects could be distinguished.

Independent variables. If internalization and identification are independent, then each must have its own determinants. Furthermore, to demonstrate that these processes do not merely reflect individual differences, it is necessary to show that they are amenable to experimental variation. Thus, independent variables were chosen that would affect the processes and facilitate their separation.

For internalization, the variable that fulfilled these purposes was the extent to which the persuasive message contained arguments that were congruent with recipients' values. The more congruent the arguments, the more readily they can be internalized. It is also possible, however, for this manipulation to affect identification. Communicators who use more value-congruent arguments might also appear attractive over and beyond the extent to which their arguments are internalized. Thus the congruence manipulation is shown as a potential determinant of both internalization and identification in the diagram.

A second variable, communicator trustworthiness, was manipulated to affect identification. Communicators who are trustworthy should be more likely to induce identification than ones who are not. At the same time, communicator trustworthiness might also affect internalization, so this causal link was also tested in the model. Trustworthy communicators may facilitate internalization because their arguments are more credible.

Finally, the product of the independent variables was included because the variables might interact in affecting either internalization or identification.

Dependent variables. It was also critical in the present research to distinguish internalization from identification at the response level. To accomplish this goal, an effect of internalization that would not be produced by identification was measured. This variable measured the extent to which respondents' attitudes are justified by the beliefs in their own value system. The justification could involve (a) beliefs that the advocated position produces benefit (proarguments) or (b) beliefs that it produces harm (counterarguments). Both of these beliefs can be represented in an expectancy–value model of attitude structure (Peak, 1955; Rosenberg, 1956) in which proarguments correspond to positive expectations of the advocated position and counterarguments to negative expectations. Thus, a single argument index is shown affected only by internalization in the diagram.

Two typical indices of attitude change (agreement with and convincingness of the message) were measured and are shown affected by both internalization and identification in the diagram. A single index of communicator trustworthiness was included to validate the corresponding manipulation. It was assumed to reflect internalization as well as identification because a communicator who presents more value-congruent arguments should also be seen as more trustworthy.

Finally, an index of attraction toward a similar other was measured. The other was described as a fellow subject who agreed with the advocated position. It was assumed that to the extent that subjects also agreed with the advocated position, their similarity and attraction toward the fellow subject would be greater. A major implication of the present model is that this process occurs as a consequence of both internalization and identification and therefore is not a pure measure of true attitude change.

Uncontrolled variation. Also shown in the diagram are sources of variation in the dependent variables that were not under experimental control. These include individual differences in internalization and identification that could be sizable. It is desirable to analyze the present model in terms of both treatment and individual variation, since similarity–attraction is so sensitive to individual variation. Furthermore, subjects' value systems

could be expected to differ greatly, producing considerable individual variation in internalization. Finally, a certain amount of error is shown affecting each dependent variable. The errors were assumed to be mutually uncorrelated, an assumption that should be (and was) evaluated.

Method

Subjects and Design

One hundred and sixty undergraduates fulfilling course requirements in introductory psychology were randomly assigned to four conditions of an orthogonal design involving two levels of value congruence and two levels of communicator trustworthiness. Equal numbers of males and females were assigned to each condition.

Experimental Variables

The intent of the manipulations was to produce change in subjects' attitudes toward the admittance of Puerto Rico to the Union. The value-congruence manipulation involved variation in the acceptability of a message that argued in favor of making Puerto Rico the 51st state. The less congruent message, an adapted version of one used by Watts and McGuire (1964), referred to the need to establish military bases in Puerto Rico and to replace those in Cuba, the international propaganda value of admitting a state composed of a minority population, and the economic advantages of eliminating import duties upon Puerto Rican goods. The more congruent message, which was written by the author, claimed that statehood would ensure a higher minimum wage for the underpaid and exploited work force, a tax structure more suited to the needs of the people, and a voice in Congress to affect the decisions that are now made without Puerto Rico's direct representation. The messages were approximately equal in length, and pretesting confirmed that they were perceived as equally well written.

The arguments were presented as a statement given by a witness for a congressional committee hearing on Puerto Rico's present and future status. The communicators were described as either a distinguished professor from the Yale law faculty who was an expert on Latin America or as a director of public relations for a land development corporation located in Puerto Rico. The public relations director was assumed to be less trustworthy because his firm might benefit from Puerto Rico's statehood; furthermore, it seemed reasonable that university students would see a law school professor as trustworthy and would be more inclined to identify with him than with a public relations person.

Procedure

Subjects were assembled in groups of 6 to 12 and were told that the experiment was concerned with their "ability to process and evaluate information." They were asked, in written instructions, to read the message carefully and to complete a questionnaire that followed the message. The questionnaire contained 14-category scales for rating the convincingness of the arguments, agreement with the advocated position, and the trustworthiness of the source.

When everyone had completed the questionnaire, the argument and attraction questionnaires were administered, their order being counterbalanced within experimental conditions. The argument questionnaire was constructed to increase the likelihood that a respondent's ability to support the advocated position would be measured. Previous research by the author (Romer, 1979) has suggested that "thought listing" procedures such as the one used by Brock (1967) do not adequately represent a respondent's repertoire of arguments and that a questionnaire specifically requesting that respondents list as many arguments as they can is a more direct measure of their ability to argue for or against an attitude position. Therefore subjects were not simply asked to list their "thoughts and ideas" about the advocated position. Instead, they were asked to consider that both positive and negative consequences can follow from an event. They were given as an example the devaluation of the dollar, which might lead to greater exports but higher prices for imported goods. Following the example, they were asked to list as many positive and negative consequences of admitting Puerto Rico as they could within a 5-minute period. At the end of the 5 minutes, both the desirability and the likelihood of the consequences listed were rated. Positive desirability was indicated by a scale of 1 to 5 ranging from "only slightly desirable" to "extremely desirable." Undesirability was rated from −1 ("only slightly undesirable") to −5 ("extremely undesirable"). Likelihood judgments were requested on a scale from 1 ("not very likely") to 5 ("extremely likely").

The attraction questionnaire was designed to measure attraction in a relatively unobtrusive manner. Rather than asking subjects how much they would like a person whose attitude was completely similar to theirs (as in Hendrick & Seyfried), the questionnaire asked subjects to imagine another subject in an experiment similar to the one in which they were participating who expressed "strong agreement" with the message they had read. Once they had "formed a picture of this person," they were asked to describe the person in terms of the likelihood that she or he possessed each of 10 traits. The ratings were made on a 10-category scale ranging from "not very likely" to "extremely likely." The traits, taken from Anderson (1968), covered the entire range of likableness and were all high in judged meaningfulness.

At the conclusion of the experiment, subjects were

invited to ask questions about the experiment and its purpose. Although the content and the occurrence of questions varied considerably across sessions, all subjects were promised written, posted feedback about the results of the experiment.

Measurement of Dependent Variables

Three of the dependent variables were simply taken from the category ratings of convincingness, agreement, and trustworthiness. Convincingness was rated in response to the question "How convincing were the arguments in the statement?" ("not very convincing" to "very convincing"). The agreement item asked "To what extent do you agree that Puerto Rico should be admitted as the 51st state?" with "strongly agree" to "strongly disagree" as polar descriptions; trustworthiness was assessed with "How truthworthy do you regard the witness to be with respect to the Puerto Rican issue? ("not very trustworthy" to "very trustworthy").

The argument index was formed by multiplying the desirability rating by the likelihood rating for each consequence that a subject listed and taking the arithmetic sum of these products as the overall index for a subject. In a similar fashion, the attraction index was obtained by multiplying the likelihood ratings by a transformation of the scale values of likableness tabled by Anderson (1968) for each of the traits. The tabled values range from 0 to 6, covering the entire range of likableness. For the purpose of this index, however, a value of 3 was assumed to reflect neutrality, with values greater than 3 deviating in a positive direction and values less than 3 in a negative direction. These deviation scores defined the trait values that were multiplied by the likelihood judgments in forming the overall index.

Analysis

The causal diagram presented in Figure 1 corresponds to an oblique five-factor model in Jöreskog's system. In this model, observed variables in the diagram (Y) are written as a function of latent factors (F) and error (E):

$$Y = AF + DE,$$

in which A is a matrix of factor loadings and D is a diagonal matrix of error coefficients. This model predicts the correlation matrix of independent and dependent variables (C) from

$$C = ABA' + D^2,$$

in which B is a matrix of interfactor correlations. The parameters of the A and B matrices as defined by the causal model are shown in Table 1.

As is evident, many parameters were predefined as zero. These restrictions are implied by the causal model and indicate that the variable or factor is predicted not to correlate with the relevant factor. Parameters that were meant to be estimated are left blank. These correspond to the causal links that were hypothesized in the diagram. Two of the restrictions are notable: (a) The loading of the argument index on the identification factor was set to zero, reflecting the assumption that identification is independent of the extent to which respondents can argue in favor of the advocated position, and (b) the correlation between internalization and identification was set to zero, reflecting the assumption that identification is independent of internalization. All of the unrestricted correlations in B refer to potential effects of the independent variable factors upon internalization and identification. The unrestricted loadings in A refer to links between factors and the various variables.

An important aspect of the present model concerns the fact that the parameters estimated under it are uniquely defined. In ordinary factor analysis, the solution is arbitrary because the factors can be rotated without violating the assumptions of the model. In the present model, the factors are defined (by the zero loadings in the A matrix) such that no other estimates of the free parameters will fit the model as well as the ones that are obtained.[2] The

Table 1
Parameters Defined by Causal Model

Variable/factor	Factor 1	2	3	4	5
Matrix *A*					
Congruence[a]	—	0	0	0	0
Trustworthiness[a]	0	—	0	0	0
Interaction[a]	0	0	—	0	0
Convincingness	0	0	0	—	—
Agreement	0	0	0	—	—
Trust	0	0	0	—	—
Arguments	0	0	0	—	0
Attraction	0	0	0	—	—
Matrix *B*					
1. Congruence	1.0				
2. Trustworthiness	0.0	1.0			
3. Interaction	0.0	0.0	1.0		
4. Internalization	—	—	—	1.0	
5. Identification	—	—	—	0.0	1.0

Note. The far left column lists variables for Matrix A and factors for Matrix B.
[a] Independent variable coded 1, −1.

[2] According to Jöreskog (1969) the criteria for a unique solution are that there are at least k^2 (where k = the number of factors) restrictions in the A and B matrices and that the rows of the A matrix can be permuted such that restrictions on the factors lie in the upper triangle of the matrix. Both of these criteria are met by the present model.

Table 2
Correlation Matrix and Means and Standard Deviations of Independent and Dependent Variables

Variable	1	2	3	4	5	6	7	*M*	*SD*
1. Value congruence								0.00	1.00
2. Communicator trustworthiness	000							0.00	1.00

7. Arguments	135	020	−046	368	397	155		15.37	46.07
8. Attraction	216	095	−058	535	429	397	466	16.93	22.56

solution, therefore, is the best that can be obtained, given the restrictions that define the factors.

There are a number of computer programs presently available to solve this causal system. The one used in this analysis was Jöreskog's analysis of covariance structures (Jöreskog, Gruvaeus, & Van Thillo, 1970). This program, as well as others, employs a large sample chi-square test of fit based on the maximum-likelihood principle. The test of fit measures the extent to which the predicted correlation matrix matches the observed matrix. The program produces a solution that minimizes the discrepancy between these matrices; however, a particular model may or may not fit the observed matrix. If a model produces a good fit, it can then be considered a candidate for explaining the data set.

Results

The correlation matrix for both independent and dependent variables is presented in Table 2. Rather than focusing upon specific correlations in the matrix, the present analysis attempts to account for the pattern of correlations in the entire matrix. Before turning to the analysis, however, it is worth asking whether the present matrix fully accounts for the effects that were observed. In particular, the order of measuring the argument and attraction indices was counterbalanced within experimental conditions, and equal numbers of males and females were studied in all cells of the design. However, neither order of measurement nor sex of subject produced any effects upon the variables in the matrix. It was assumed, therefore, that the data set was adequately described by the correlations in the matrix.

The results of the covariance structure analysis are shown in Figure 1. The first question one can ask is whether the correlation matrix is adequately reproduced by the model. The answer appears to be yes. The chi-square test of fit between the predicted and obtained correlation matrix was nonsignificant, $\chi^2(10) = 3.55$, $p = .96$, indicating a close correspondence between predicted and obtained values. Inspection of the differences between these values revealed that no residual was greater than .07 in absolute value ($M = .006$, $SD = .021$). Thus, the model does a good job of predicting the data.

As is evident in the figure, factors corresponding to both internalization and identification mediated variation in the dependent variables. All of the dependent variables loaded positively upon internalization, indicating that respondents who had positive attitudes also thought the communicator was trustworthy, had arguments to support their position, and were attracted toward others who agreed with the advocated position. A factor corresponding to identification, however, was orthogonal to internalization and mediated variation that was independent of arguments that supported the advocated position. It contained loadings from all of the other dependent variables, indicating that the more respondents agreed with the advocated position, the more they trusted the communicator and the more attracted they were to others who agreed with the advocated position. Thus, as expected, attraction toward others was affected by both internalization and identification.

An important assumption of the causal model is the theoretical independence of internalization and identification. As they are

defined, both involve variation in expressed attitudes and attraction toward those who hold the same attitudes, but only internalization is based on arguments in support of the attitude position. Although the goodness-of-fit test indicates that this assumption is plausible, it is also possible to test the model without making the assumption. In this test, the model is fitted without the B-matrix restriction that the factors are uncorrelated. The obtained solution, however, was virtually identical to the one in Figure 1, and the factors were still orthogonal ($r = -.02$). It appears, therefore, that relaxing the assumption does not improve the fit of the model and that the assumption is valid.

In evaluating the effects of the independent variables upon internalization and identification, a special procedure was employed. The obtained correlation (shown in the figure) was set to zero, and the remaining parameters of the model were fixed to their obtained value. The model was then tested to see if the goodness of fit of the entire model was significantly poorer than the fit of the original model. If it is, then the correlation can be considered to be different from zero.

As expected, the value congruence manipulation affected internalization, $\chi^2(1) = 4.38$, $p < .05$. The message that contained more congruent arguments was more readily internalized. There were no other effects upon internalization, however. Apparently, the trustworthiness of the communicator did not affect the credibility of his persuasive arguments.

The trustworthiness manipulation did affect identification, however, $\chi^2(1) = 14.03$, $p < .05$. The more trustworthy communicator apparently induced greater change by virtue of his attractiveness. In addition, the value congruence of the message affected identification, $\chi^2(1) = 5.42$, $p < .05$. Thus the congruence manipulation produced change mediated by both internalization and identification. The interaction of the independent variables did not affect identification, however.

As is evident in Figure 1, uncontrolled sources of variation in both internalization and identification were sizable. This indicates that most of the variation in the mediators was due to individual differences. Nevertheless, the success of the model suggests that both treatment and individual variation can be encompassed by the same causal model.

The estimated errors shown in the Figure indicate that from 40% to 64% of the variation in the dependent variables was unexplained.[3] The assumption that these errors of measurement are uncorrelated does not seem unreasonable in view of the very close fit of the model. That is, there does not appear to be any reliable variation in the dependent variables that was not explained by the internalization and identification factors. Furthermore, the finding that both factors were affected by the independent variables suggests that the factors are not solely composed of error. Although the error variation in the variables was sizable, all of the remaining error-free variation (36% to 60%) was predicted by the model.

Rival Models

Even though a particular model does well in predicting data, it is always possible that an alternative model is superior. One advantage of causal analysis, however, is that the assumptions underlying a model are made explicit so that different models can be tested. For example, it is possible that all of the reliable variation in the dependent variables is accounted for by a single internalization factor. Therefore, a model containing only internalization was fitted to the data. This model was identical to the favored model with the exception that the identification factor was not included. This model did not fare well, however, by the goodness-of-fit test, $\chi^2(17) = 27.67$, $p < .05$. Furthermore, the two-factor model was a significantly better predictor of the correlation matrix than the internalization model was, $\chi^2(7) = 24.12$, $p < .05$. It appears, therefore, that a model involving both internalization and identification is a better explanation of the data than a model involving only internalization is.

---

[3] The estimated proportion of variance due to error in each dependent variable is equal to the square of the corresponding error coefficient.

The possibility exists, nevertheless, that a different two-factor model also accounts for the data. To evaluate this possibility, alternative models that contained different restrictions on the second dependent variable factor were constructed. These included (a) restrictions on both attitude measures so that the second factor only contained loadings from trust, arguments, and attraction; (b) a restriction on trust so that all of the remaining variables could load on the factor; and (c) a restriction on attraction, with the remaining dependent variables free. Although each of these models provided a good fit to the data, the solutions that were obtained were uninterpretable. Two of them (a and c) implied that the variables on the second factor were inversely correlated but positively affected by the independent variables; the third implied that congruence had a negative impact on all the variables of the second factor. Thus although these models could fit the data mathematically, they did so at the expense of plausibility and interpretability. This is not surprising, since there were no obvious theoretical models that would support these solutions. Nor could the second factor in these solutions be attributed to correlated measurement error: The factors in each model were correlated with the independent variable factors suggesting that if these models were valid, the factors were not entirely composed of error. Thus, the tests of these alternative models suggest that the internalization–identification model is the best explanation of the data.

Discussion

There were three things to be demonstrated in the present research. The first was that internalization and identification independently mediate attitude change. This, of course, was the rationale underlying the two-factor model. This model did significantly better in predicting the data than did a model containing only internalization as a mediator. Furthermore, the separate effects of the independent variables upon internalization and identification indicate that each factor reflected valid variation in the dependent variables. In fact, the value-congruence manipulation affected both mediators, but trustworthiness only affected identification. Finally, a test of the model without the orthogonality assumption still affirmed the independence of the factors. Thus, two orthogonal factors appeared to mediate attitude change in the present laboratory setting.

The second goal of the research was to show that internalization is a more central process than identification is in mediating attitude change. This was demonstrated by restricting the argument index from loading on the identification factor. Since subjects were asked to generate as many positive and negative arguments as they could (in 5 minutes), the argument index has face validity as a measure of a respondent's ability to support the advocated position. Therefore only the internalization mediator reflected variation in the perceived consequences and justification of the advocated position. Although the argument index was only one of many possible measures of internalization, it did display validity by correlating with the other measures. Furthermore, the finding that trustworthiness affected identification but not internalization indicates that there were effects that were mediated by processes other than internalization. Therefore, even if a more sensitive measure of internalization had been used, the present results suggest that a separate factor would still be needed to explain variation that is unrelated to internalization.

The third goal of the research was to show that attraction toward similar others is a function of both internalization and identification. This hypothesis was clearly supported. The attraction index loaded on each factor, indicating that variation in attraction was affected by both internalization and identification. Apparently, we express acceptance of an advocated position not only because we can argue in favor of it but also because we identify with others who hold the same opinion. Therefore, Hendrick and Seyfried (1974) were justified in measuring attraction as an indicator of true attitude change. However, the present results show that without evidence about whether or not

internalization has occurred, it is not possible to know whether attraction reflects internalization or identification.

Wells' (1976) charge that attitude change and attraction may both be caused by experimental artifacts (demand characteristics and evaluation apprehension) seems an unlikely explanation for the present results. Since attitudes and attraction loaded on each of *two* factors, one would have to postulate a complex pattern of compliance motives to account for both factors. In the case of internalization, subjects would be assumed to have role played greater acceptance of the more congruent message. However, since all subjects received a persuasive message of comparable length and writing quality, demands for expressing acceptance of the advocated position should have been equal in both congruence conditions. Furthermore, the instructions for generating arguments requested subjects to list as many arguments as they could. If anything, this instruction should have induced demands to be prolific rather than to be favorable toward the advocated position. Finally, if the internalization factor merely reflects compliance, it is unclear why the factor would not also be affected by source trustworthiness.

Whether the identification factor reflects experimental artifacts is less certain. However, attraction was measured less obtrusively than in Hendrick and Seyfried (1974), and, even if compliance contributed to the identification factor, the conclusion that more than one form of attitude change mediated the results would still be tenable. Thus although it is impossible to rule out completely a compliance explanation, it seems unlikely that compliance can account for the entire pattern of the present results.

One implication of the present approach is that, if subjects' attitudes were retested at a time when the message and source were less salient, attitudes based on internalization should be more stable than those based on identification. Kelman (1958) used this assumption to show that compliance, identification, and internalization could be distinguished. The present results are consistent, therefore, with research on the persistence of attitude change in which variation due to communicator trustworthiness decays at a different rate from "message-only" variation once "dissociation" of the source has occurred (Gruder, Cook, Hennigan, Flay, & Halamaj, 1978; Hovland & Weiss, 1951). The basis of this differential decay could be that trustworthiness is mediated by identification more than by internalization.

One advantage of the present causal modeling approach is that both individual and treatment variation could be tested in the same analysis. It was possible, therefore, to observe the similarity–attraction relationship at both the individual and treatment levels. Although the variation in individual attitudes and attraction was far greater than the treatment variation, both appeared to be subsumed by the same causal processes.

The present results indicate that laboratory-produced attitude change may be valid. This is cause for optimism on at least two grounds. First, although the study of attitude change was once a central issue in social psychology, interest in the topic has waned. Researchers doubt the validity of studying attitude change in the laboratory, and the results that have been obtained are regarded with suspicion. Although there are probably many reasons for the reduced interest, the present results suggest that suspicion of the laboratory is not always justified. Second, if genuine attitude change can be distinguished from other forms of change, the study of attitude change can proceed despite the belief that laboratory-induced persuasion is suspect. For example, research can be conducted further to determine how and when a message is internalized. Thus even if the many variables that have been studied only produce surface change, this realization need not impede progress toward determining the factors that cause long-lasting and meaningful change in peoples' attitudes.

Attitudes and Cognitive Response: An Electrophysiological Approach

John T. Cacioppo
University of Iowa

Richard E. Petty
University of Missouri—Columbia

Two experiments employed electrophysiological procedures for assessing the covert information-processing activity of message recipients. In Experiment 1, 24 subjects expected to hear discrepant communications and were requested to "collect their thoughts" following each forewarning. As discrepancy increased, anticipatory counterargumentation increased, whereas production of favorable thoughts and agreement decreased. In addition, following forewarnings oral muscle, cardiac, and respiratory activity increased, whereas nonoral muscle activity remained constant and quiescent. In Experiment 2, 60 subjects anticipated and heard a proattitudinal, a counterattitudinal, or a neutral communication. They evaluated more positively and generated more favorable thoughts and fewer counterarguments to the proattitudinal than to the counterattitudinal advocacy, but rated similarly the neutral and proattitudinal advocacies. As in Experiment 1, incipient oral muscle activity increased following the forewarning of an involving *counterattitudinal* advocacy; it also increased for all conditions during the message. Patterns of subtle facial muscle changes reflected the affective nature of the cognitive responding before and during the message. These results provide evidence that electrophysiological assessments offer objective, concurrent, and independent measures of cognitive response in persuasion, and support the notion of recipients as active information processors when topic involvement is high.

Recent work in attitude change has emphasized the manner in which persons process the information contained in persuasive messages. Investigators have studied how such variables as source credibility (Cook, 1969; Gillig & Greenwald, 1974), distraction (Petty, Wells, & Brock, 1976), message repetition (Cacioppo & Petty, 1979), message comprehensibility (Eagly, 1974), forewarning of persuasive intent (Petty & Cacioppo, 1979a) and of topic and position (Petty & Cacioppo, 1977), number of arguments employed (Calder, Insko, & Yandell, 1974), issue involvement (Petty & Cacioppo, 1979b), heart rate (Cacioppo, 1979), group discussion (Burnstein & Vinokur, 1977), and so forth affect the profile of cognitions (e.g., counterarguments, favorable thoughts, neutral thoughts), and attitude change. Theoretical interest in the influence on persuasion of a person's idiosyncratic cognitive responses to an advocacy is certainly not new (cf. Hovland, Lumsdaine, & Sheffield, 1949), but the present level of research activity in the area marks a shift in emphasis toward this approach (cf. Petty, Ostrom, & Brock, in press). The reinvigorated interest in these covert thought processes stems in part from the apparent inability of classical learning theories to provide parsimonious accounts of observed attitude changes (Greenwald, 1968; Petty, 1977),

The authors thank Anthony G. Greenwald, Curt A. Sandman, and the action editor for comments concerning this research; Charles W. Snyder for technical advice and assistance; Keith Richenbacher, Debra Horowski, and June Chen for assistance in Experiment 1; and Leo Quintanar, Kevin Smith, and J. P. Holbrook for assistance in Experiment 2. This material is based on work supported in part by National Science Foundation Grant BNS-7818667.

and in part from improvements in measurement procedures (Brock, 1967; Cacioppo, Harkins, & Petty, in press).

We now know that the level of cognitive responding to an advocacy can vary from complete inattention or simple structural (e.g., orthographic) analyses of the message to extensive semantic examination and cognitive elaboration. The latter, but not the former, allows recipients to determine the implications of an event for themselves and for significant others (Cacioppo, Glass, & Merluzzi, 1979; Craik & Tulving, 1975; Janis & Mann, 1977; Rogers, Kuiper, & Kirker, 1977) and appears to be an important determinant of attitude change (cf. Petty et al., in press). On the other hand, the cognitive response (information-processing) approach to persuasion has been questioned in recent years (Baron, Baron, & Miller, 1973; Langer, Blank, & Chanowitz, 1978; Miller & Baron, 1973; Romer, 1979). The self-report measures of cognitive response have been criticized for placing post hoc demands on subjects to report rational(izing) processes for their attitude change. These critics have called for direct, concomitant measures of cognitive activity in persuasion.

Perhaps the most commonly used measure of cognitive response in persuasion is the "listed thoughts" procedure developed by Brock (1967) and Greenwald (1968). Inspection of the existing data regarding the reactivity and reliability of the thought-listing procedure is encouraging. The same pattern of attitudinal responses has been reported in groups that list and do not list their thoughts (Petty & Cacioppo, 1977), and the order of attitude and cognitive response assessment has not affected either measure (Calder et al., 1974; Petty et al., 1976). Third, split–half and test–retest reliability of attitude and cognitive response measures are satisfyingly high (Cullen, 1968). Nevertheless, it can still be argued that requesting subjects to list their thoughts produces responses that would not and do not occur naturally.

Hence, we believed it worthwhile to develop a concurrent measure of cognitive and affective response that could be obtained without the subject's knowledge of its purpose and that would not require the subject to emit a voluntary response. An electrophysiological approach seemed promising:

> It is possible that a hypothetical construct, hypothesized to be a covert response (r), may be directly measured as an electromyogram that occurs after the external stimulus, but before an overt response—(indeed) the covert electromyographic response may be an antecedent or determiner of the following overt response. (McGuigan, Culver, & Kendler, 1971, p. 146)

Thus, by studying electrophysiologically the microprocesses operating in a persuasion setting, much may be learned (i.e., confirmed or disconfirmed) about the presence and nature of the postulated cognitive-response processes.

Fortunately, psychophysiological research has yielded a few biocognitive relationships that make the present endeavor simpler and more assuredly informative. McGuigan and his colleagues, for instance, have amassed substantial data illustrating the sensitivity and reliability of the electromyogram (EMG), particularly of the speech muscles, as an index of covert linguistic activity (for reviews, see Garrity, 1977; McGuigan, 1970, 1973b, 1978; Sokolov, 1972). Also, cardiac activity has been shown to accompany covert information processing, with a decelerated heart rate characteristic of sensory acuity or reception, and an accelerated heart rate characteristic of cognitive elaboration (e.g., Cacioppo & Sandman, 1978; Lacey, Kagan, Lacey, & Moss, 1963; Schwartz & Higgins, 1971). A brief overview of these areas of research is provided next.[1]

Electromyographic Specificity and Cognitive Responding

A conception held generally about the EMG activity of the speech muscles (when this

[1] This discussion is certainly not exhaustive of the psychophysiological responses indicative of mental activity. A few notable exclusions are the pupillary (Goldwater, 1972; Kahneman, 1973) and averaged evoked (cortical) responses (Posner, 1975). The interested reader may wish to consult McGuigan and Schoonover (1973) or Greenfield and Sternbach (1972) for additional information about these measures.

tivity reflects subvocal speech) is that the sultant afferentiation traveling from these uscles to the language centers of the cortex an aid to stimulus comprehension, elabora- on, and abstraction (Hardyck & Petrinovich, 969; McGuigan, 1973a, 1978; Sokolov, 967, 1972). Specifically, the afferentiation om the speech muscles appears to serve as nonmeaningful but redundant phonetically ded representation of the immediately pre- ding efferent language commands, which riginate in the cortex and result from (some- mes preliminary) processing of external and emorial stimuli. This redundancy serves to rengthen, in a manner similar to that of gnitive rehearsal, the links between the ex- rnal event and the internal representations. ltimately, as the links between the external imulus and the resulting (overt) response come established (e.g., automated), less dundancy is needed and less speech EMG tivity is in evidence.

Consistent with these notions, Sokolov 1969) reported that subjects performing a mplex matrix manipulation exhibited bursts covert oral EMG activity at first. Repeated ials with the task, however, resulted in a turn of the EMG activity to basal levels. milarly, nonproficient readers display reater oral EMG activity while reading than proficient readers—but both groups dis- ay elevated oral EMG activity when read- g difficult material (McGuigan, 1967; Mc- uigan & Bailey, 1969b; McGuigan, Keller, Stanton, 1964); greater oral EMG activity present when persons read silently than hen they process nonlinguistic materials .g., music); and the silent processing of oth linguistic and nonlinguistic stimuli leads increased oral EMG activity compared to aseline measures (McGuigan & Bailey, 969a).

Further, these changes in oral EMG do not flect simple changes in the general somatic autonomic arousal of the organism: A con- omitant increase in EMG activity is not ob- rved in irrelevant (e.g., nonlinguistic) uscle groups (cf. McGuigan, 1970; Sokolov, 969); nor has the galvanic skin response een related to oral EMG during the silent erformance of language tasks (Sokolov, 1969, 1972); and quickened breathing is observed during silent reading, presumably reflecting subvocalization (McGuigan et al., 1964; McGuigan & Rodier, 1968). Finally, the EMG responses of the speech muscles are highly specific. Collectively, these results suggest that oral EMG activity *can* reflect information processing in persuasion.[2]

Cardiac and Cognitive Activity

Contemporary investigations of changes in heart rate and covert information processing have included: (a) monitoring heart rate and performance during the anticipation and performance of a wide variety of cognitive (e.g., sentence generation) and sensory (e.g., viewing flashing lights) tasks (e.g., Lacey, 1959; Lorens & Darrow, 1962); (b) the measurement of the differences in heart rate change during task performance by individuals who differ dispositionally in their mode of information processing for that task (e.g., Blatt, 1961); (c) the manipulation of attributes of the task (e.g., processing requirements) while monitoring heart rate and accompanying physiological responses (e.g., Blaylock, 1972; Tursky, Schwartz, & Crider, 1970); (d) monitoring heart rate and general somatic activity during the anticipation and performance of tasks under varying levels of incentive or motivation (e.g., Elliott, 1974; Obrist, Webb, Sutterer, & Howard, 1970); (e) monitoring sensory thresholds, reaction time, or cognitive and attitudinal responses following endogenous changes in heart rate (e.g., Cacioppo,

[2] Festinger and Maccoby (1964) were among the first persuasion researchers to discuss the subvocalizations of a recipient in response to a persuasive appeal. Keating and Brock (1974) pursued the notion that a recipient's subvocalizations may contain rich evidence regarding what was happening to the stimulus between the time the subject heard it and responded overtly to it. However, these efforts were largely unsuccessful empirically, due to the insensitive procedures employed; no direct electrophysiological measurement of speech EMG activity in a persuasion setting has ever been reported. Moreover, previous discussions of subvocal activity in persuasion have focused *solely* upon the *counterarguing* process, whereas we focus here on more general cognitive-response processes.

Sandman, & Walker, 1978; Edwards & Alsip, 1969); and (f) observing the cognitive and attitudinal effects of exogenously manipulated heart rate (Cacioppo, 1979). The cardiac response generally covaries with the cognitive requirements or difficulty of the task, particularly when the task requirements are substantial. Although considerable controversy still exists in psychophysiology regarding the neurophysiological and/or biological processes controlling the heart rate responses observed in the aforementioned studies, the empirical link between the cardiac response and cognitive activity seems well established. Whether the cardiac acceleration observed during the performance of cognitive tasks is initiated by a metabolic control center (cf. Obrist et al., 1970) or by a modulating negative feedback system (cf. Lacey, 1967) is unimportant here. Central to the present study is the finding that the cardiac response reflects considerable changes in cognitive activity, even when these changes are spontaneous and self-induced (Schwartz, 1971; Schwartz & Higgins, 1971).

Methodological Considerations

Several methodological safeguards were instituted here to assure that the electrophysiological measures we observed reflected covert information processing. First, a measure of general (nonlinguistic) somatic activity was obtained in addition to the measures of oral EMG and cardiac activity. To the extent that the activation is specific to the speech muscle fibers and heart rate when processing an external event, we are more confident that we have tapped covert processing rather than irrelevant (i.e., unreliable) movements, postural shifts, and so forth. Second, the level of heart rate and EMG activity observed while anticipating and processing the stimulus was compared with prestimulus measures to assess whether or not electrophysiological "response" actually occurred (McGuigan, 1970). And third, Miller and Baron (1973) have suggested that observations of oral EMG (and cardiac) activity may not differentiate the cognitive elaboration of the advocacy from the covert rehearsal of the arguments constituting the persuasive message. One of our aims was to determine the *existence* of cognitive-response processes in persuasion; hence, we obtained recordings of the electrophysiological measures while subjects were *anticipating* highly involving and counterattitudinal advocacies as well as while subjects were processing them. A good deal of evidence documenting that anticipating a discrepant and involving message evokes issue-relevant cognitive responding has accrued using the thought-listing procedure (Cacioppo, Petty, & Snyder, 1979; Petty & Cacioppo, 1977; Cialdini & Petty, in press).

Experiment 1

The aim of Experiment 1 was primarily methodological. We sought to test the utility of an electrophysiological assessment of cognitive response. To do so, we forewarned individuals that they would hear a (counterattitudinal) message and we asked them to "collect their thoughts" about the issue. Immediately preceding our forewarning, we collected basal measures of physiological response, and we continued to record these meaures while the individuals were anticipating the discrepant message (i.e., when they presumably were following instructions and were generating cognitive responses concerning the advocacy). We expected oral EMG and cardiac activity, but not general somatic activity, to be heightened during the "collect thoughts" interval, compared to basal levels.

Confirmation of these expectations would illustrate the applicability and utility of electrophysiological techniques for studying cognitive response in persuasion. Obtaining these results would *not*, of course, provide evidence that cognitive responses in persuasion are generated naturally, since we asked the individuals to collect their thoughts following the forewarning. A second experiment addressed this latter issue.

A second aim of Experiment 1 was to explore the effects of affect- and nonaffect-laden cognitive responding on electrophysiological response patterns. Neither oral EMG (cf. Garrity, 1977; McGuigan, 1978) nor cardiac activity (Cacioppo & Sandman, 1978; Harris, Katkin, Lick, & Habberfield, 1976) appear to

distinguish the types of affective response evoked, though differentiation between affect- and non-affect-laden thought sequences using heart rate has been observed (Schwartz, 1971). The discrepancy of the impending advocacy was manipulated in Experiment 1 to obtain gradations of affect-laden processing to assess its physiological effects. Additionally, the thought-listing procedure was used to explore the relationships among the cognitive (e.g., favorable thoughts, counterarguments, neutral/irrelevant thoughts) and electrophysiological (e.g., oral EMG, heart rate) responses.

Method

Subjects and Design

Three replications of eight male undergraduates were conducted. Subjects were tested individually, with assignment to replication determined randomly. A $3 \times 3 \times 2 \times 2$ mixed design was employed in which the three replications served as a between-subjects factor, and levels of communication discrepancy (low, moderate, and high), two different topics within each level of discrepancy, and interval during which electrophysiological measures were recorded (prewarning baseline and postwarning "collect thoughts" interval) served as within-subjects factors. (The interval factor was relevant only to the analyses of the electrophysiological measures.)

Materials

A separate audiotape was prepared for each of the three replications. Each tape contained the experimental instructions and six announcements regarding the source of, topic of, and position to be advanced in an upcoming message. (In fact, however, the messages were never presented.) Each level of discrepancy for each topic appeared in one replication. The tapes (i.e., replications) differed in the order of the topics, which was determined randomly for each replication. The experimental stimuli are displayed in Table 1.

Procedure

When subjects arrived at the laboratory, they were placed in a sound-attenuated room and were seated in a comfortable chair. Electrodes were attached for measuring oral (orbicularis oris—lips; digastricus—chin; platysma—throat) EMG activity, nonspeech (trapezius—back) EMG activity, heart rate, breathing rate, and cephalic pulse amplitude. A 5-minute adaptation period preceded the experimental trials.

Subjects were told that in about 40 minutes they would hear several different messages having direct consequences for undergraduates, and that before the presentation of the messages we should like to obtain their comments on and evaluations of the position (i.e., advocacy) to be advanced in each message. The subjects were asked to sit quietly and collect their thoughts for the minute following each announcement; then, at the experimenter's signal, subjects were asked to list everything about which they had been thinking (subjects were given 3 minutes to do so), to rate their agreement with the upcoming advocacy, and to complete several ancillary measures (i.e., felt effort, involvement, distraction, and responsibility). The nature of these forms is described in detail in Petty and Cacioppo (1977). The forewarning, collect thoughts, and thought-listing intervals were repeated six times to cover six different topics, each separated by a variable intertrial interval (ITI) ranging from 90 to 120 seconds. Each ITI was initiated when the experimenter requested the subjects to "please sit quietly for the next minute or so." The final 60 seconds of each ITI served as the baseline measure for the subsequent 60-second "collect thoughts" interval.

Chin muscle activity. Two Grass E5S cup electrodes filled with Grass EKG Sol were placed on the midline of the chin; the first was placed 1.8 cm above the point of the chin and the second was

Table 1
Experimental Stimuli

Source	Topic	Discrepant position		
		Low	Moderate	High
University board of regents	Increasing student tuition by . . .	$5.00	$40.50	$90.00
State medical association	Increasing drinking age to . . .	19 years	21 years	25 years
Member of state legislature	Increasing gasoline sales tax by . . .	2¢	5¢	10¢
University faculty committee	Graduate students teaching all . . .	freshmen	freshmen & sophomores	freshmen & juniors
President of the university	Extending finals by . . .	2 days	5 days	9 days
County municipal courts	Increasing traffic fines by . . .	25%	100%	300%

placed 1.8 cm below the point of the chin. Following Cacioppo et al. (1978), chin muscle activity was calculated for the 60-sec intervals of interest using the following formula:

$$\text{Activity index} = \sum_{i=1}^{n} \frac{(l_i \times s_i)}{l_i}$$

where s_i is the scale value of a particular amplitude of EMG activity (larger amplitude EMG activity was assigned larger scale values; scale values ranged from 0, for deflections 2 mm or less, to 5, for deflections exceeding 2 cm); l_i is the total horizontal length (i.e., time) of a particular scale value of EMG activity measured in millimeters; and n is the number of distinct instances of a particular amplitude of EMG activity. The data were quantified in this manner for the 60-sec baseline and collect thoughts intervals.

Lip muscle activity. Two Grass E5S cup electrodes filled with Grass EKG Sol were placed 1 mm below the bottom lip; each was placed .5 cm in from the ends of the mouth. Lip muscle activity was calculated using the activity index described above.

Throat muscle activity. Two Grass E5S cup electrodes filled with Grass EKG Sol were placed off midline of throat; the first was placed approximately 1.0 cm to the right of and level with the midpoint of the throat, and the second was placed approximately 1.0 cm to the left and 1.0 cm above the midpoint. Throat muscle activity was calculated using the activity index described above.

Back muscle activity. Subjects were asked to place their fingertips on their collarbone while the electrodes were secured. Two Grass E5S cup electrodes filled with Grass EKG Sol were placed over the trapezius muscle group. The first was placed 4.0 cm outward from the midline of the line passing between the first thoracic and seventh cervical vertebrae, and the second was placed halfway between the spine and the head of humerus (near the point of the shoulder). Back muscle activity was calculated using the activity index described above.

Heart rate. Grass E5S cup electrodes filled with EKG Sol were placed over the lower left rib cage and the right collar bone. The signal was amplified by a Grass wide-band AC preamplifier. Heart rate was calculated by counting the number of beats that occurred in the 1-minute intervals of interest.

Breathing rate. The respirometer was a sliding piston (consisting of a photocell and a small light) mounted on an elastic band and placed around the subject's chest (Shmavonian, Miller, & Cohen, 1968). Breathing rate was calculated by counting the number of cycles (to the nearest half cycle) occurring in the intervals of interest.

Cephalic pulse amplitude.[3] A photoplethysmograph was placed over the supraorbital notch (above the eyebrow), providing a relative measure of blood volume in the supraorbital artery. The photoplethysmograph was comprised of three light-emitting diodes (LED), radiating 100 μW of light output at 660 nanometers. The LEDs were spaced at 120° on a radius of 6.3 mm around a high-speed photoconductor, and resistance changes were recorded with a Grass oscillograph. Cephalic pulse amplitude was calculated for the intervals of interest using the following formula:

$$\text{Amplitude index} = \frac{\text{pulse amplitude in mm} \times \text{total mV/cm calibration}}{\text{standard sensitivity in mV/cm}}$$

where total mV/cm was the sensitivity of the preamp settings for a given subject, and the standard sensitivity was 1 mV/cm.

Data reduction. Physiological processes were monitored during the 1 minute preceding and following each of the six forewarnings. Persons scoring the electrophysiological data were unaware of the experimental hypotheses and of the treatments with which the data were associated.

The Grass Model 7 polygraph used in the experiment was equipped with three preamplifiers capable of measuring electromyographic activity. Since four EMG measures were of interest in the experiment, a random procedure was used to determine which three of the four EMG measures would be recorded for each subject within a replication. However, all electrode placements were prepared on each subject, and the subject was unaware of the dummy electrode placements. Difference scores relative to the prewarning levels were computed for each electrophysiological measure.

The subjects classified their cognitive response in a manner described by Petty and Cacioppo (1977): After listing their thoughts, subjects were instructed to place a plus (+) next to those thoughts that were in favor of the advocacy, a minus (−) next to those thoughts opposed to the advocacy, and a zero (0) next to those thoughts that were either neutral toward or irrelevant to the advocacy. Frequency counts served as measures of cognitive response.

---

[3] A photoplethysmograph was placed over the supraorbital artery just above the eye. The amount of light reflected back onto the photoplethysmograph is inversely proportional to the amount of blood between the photoplethysmograph and the supraorbital notch (over which it was placed). Brain blood perfusion was assumed to be indirectly related to the relative volume changes of the pulse wave that traveled to the brain via the supraorbital artery. Pulse rate was not considered to be important because of the venous return mechanism, which drains the blood from a given body area at approximately the same rate as the blood is delivered to that area (Wallace & Wallace, 1968). The validity of this measure, however, has not yet been firmly established. The plethysmograph used in these studies was developed by Robert Isenhart. More information about the plethysmograph is provided in Sandman, McCanne, Kaiser, and Diamond (1977).

Results and Discussion

Measurements of the seven electrophysiological dependent measures (chin, lip, throat, and back EMG activity, heart rate, breathing rate, and cephalic pulse amplitude) were obtained the minute preceding and following each forewarning. Parametric analyses of the questionnaire data were conducted while nonparametric analyses of the electrophysiological data were conducted, since the latter data were not distributed normally (cf. Schwartz, Fair, Salt, Mandel, & Klerman, 1976a, 1976b).

Cognitive Response, Agreement, and Ancillary Measures

We expected topic-relevant cognitive responding and agreement to be affected in a particular manner by discrepancy, but we had no particular expectations regarding neutral thought production and the ancillary measures. Hence, we set the experimentwise error rate at .10 and distributed this protection unequally across the tests (i.e., .05 for counterargumentation, favorable thought production, and agreement; .05 for the remaining five measures). We used Bonferroni-adjusted critical values for all tests, conducted two-tailed tests throughout, allocated 99% of the alpha associated with the contrasts for the first set of variables into the tail corresponding to the predicted direction of the effect (saving 1% as acknowledgment that opposite rather than predicted results sometimes obtain), and allocated 50% of the alpha associated with the tests for the second set of variables into each tail.[4] Further, the Huynh and Feldt (1970) test for the homogeneity of treatment–difference variance (HOTDV) was conducted for each dependent measure (cf. Harris, 1975, pp. 125–127).[5] These tests revealed a violation of the HOTDV assumption only for the measure of neutral thoughts, $\chi^2(2) = 8.11$. Neutral thought production was unaffected by discrepancy even with a positively biased F ratio.

The means for all cognitive response, agreement, and ancillary measures are summarized in Table 2. The analyses indicated that increasing the discrepancy between the subjects' initial positions and the advocated position led to more anticipatory counterargumentation, $F(2, 42) = 8.80$, $p < .01$; production of fewer anticipatory favorable thoughts, $F(2, 42) = 3.70$, $p < .017$; and greater felt effort in preparing cognitively for the message, $F(2, 42) = 5.33$, $p < .01$. One additional test approached significance: Agreement tended to decrease as discrepancy increased, $F(2, 42) = 3.57$, $p < .019$. No other effect or interaction was statistically significant. This pattern of results is similar to that obtained in prior research on cognitive response and agreement as a function of communication discrepancy (Brock, 1967; Cacioppo, 1977).

Table 2
Mean Responses to Thought Listing and Questionnaire Measures for Low, Moderate, and High Levels of Communication Discrepancy: Experiment 1

Measure	Mean		
	Low	Moderate	High
Primary			
Agreement	4.08	3.96	2.67
Counterarguments	2.04	2.73	3.40
Favorable thoughts	1.33	1.00	.63
Neutral thoughts	1.04	.77	.58
Ancillary			
Effort	7.35	8.42	8.42
Involvement	7.50	8.60	8.56
Distraction	3.98	3.40	2.90
Responsibility	6.81	7.96	7.42

Note. Entries for cognitive response measures indicate the mean frequency obtained in thought listings. Entries for questionnaire items are mean response to 11-point scale items in which higher numbers indicated more agreement, effort, involvement, distraction, and responsibility. Twenty-four subjects received two forewarnings at each level of discrepancy.

Electrophysiological Measures

We hypothesized that the activity of the oral muscles and heart rate would increase

[4] Required for statistical significance by these adjustments were ps $< .017$ for counterarguing, favorable thoughts, and agreement, and ps $< .01$ for the remaining measures.

[5] We are indebted to Richard Harris for providing a computer program with which to test the HOTDV assumption.

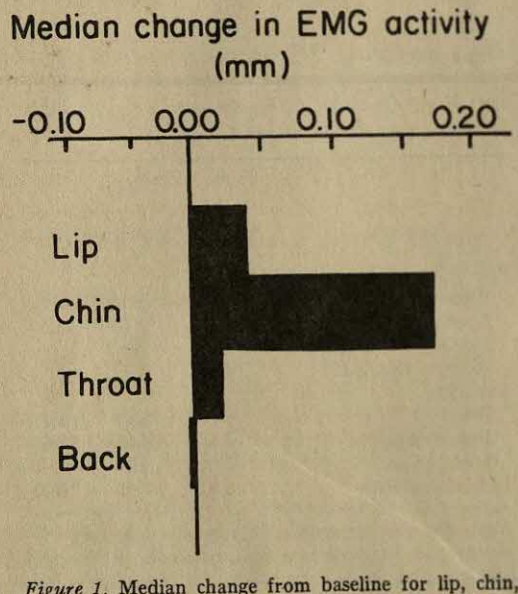

Figure 1. Median change from baseline for lip, chin, throat, and back electromyographic (EMG) activity following a forewarning about an impending counterattitudinal advocacy.

during the collect thoughts interval (relative to basal levels), since we expected cognitive response processes to be reflected electrophysiologically. Strong support for the hypothesis was obtained (see Figure 1). Oral EMG activity was elevated significantly after forewarnings of involving counterattitudinal communications (by the Wilcoxon Test: lip, $p < .001$; chin, $p < .001$; throat, $p < .10$). Also evident in Figure 1, general somatic activity, as measured by back EMG activity, was not altered by the anticipation of the counterattitudinal message ($p > .25$). The Wilcoxon Test for changes from baseline revealed that heart rate ($Mdn = 2.00$ bpm, $p < .02$) and breathing rate ($Mdn = 1.0$ cycle/min, $p < .01$) increased following the forewarning as well, whereas cephalic pulse amplitude was left unchanged ($Mdn = 0.00$). No other comparisons were significant statistically.[6]

Correlational Analyses

The affective intensity of the cognitive responses, which was varied by increasing communication discrepancy, did not affect the electrophysiological activity monitored in this study. Canonical correlations between the cognitive responses (i.e., counterarguments, favorable thoughts, neutral/irrelevant thoughts) and the relevant electrophysiological measures (i.e., lip, chin, throat, and cardiac activity) were computed within each level of discrepancy to determine whether the predicted relationship between cognitive and electrophysiological activity existed and to explore whether any association existed between the affective nature of the covert processing and electrophysiological activity. The correlations were respectable ($r = .47$ for low discrepancy conditions; $r = .44$ for moderate discrepancy conditions; and $r = .64$ for high discrepancy conditions). When a canonical correlation was calculated, collapsing across the levels of discrepancy, a coefficient of .42 was obtained.

Furthermore, the electrophysiological *specificity* obtained in this research is in striking contrast to the massive and diffuse arousal associated with the fight-or-flight reaction of extreme emotional states (Cannon, 1927) and misattribution phenomena (Schachter, 1964; see also, Rhodewalt & Comer, 1979).

The calculation of within-cells correlations among cognitive responses and agreement revealed that anticipatory counterargumentation correlated negatively with agreement ($r = -.67$, $p < .01$), favorable thoughts ($r = -.67$, $p < .01$), and neutral thoughts ($r = -.45$, $p < .01$). Favorable thoughts correlated positively with agreement ($r = .72$, $p < .01$).[7]

---

[6] Subjects were asked to count to five aloud and to move and tense slightly in their chair before the completion of the experiment to assess the validity of the EMG electrode placements. Trapezius EMG activity increased during body tensing and movements. Lip and chin EMG activity increased during overt oral behavior (counting aloud), whereas the throat EMG placement proved to be a relatively insensitive measure.

[7] Analysis of covariance procedures were employed to explore some of the possible causal sequences of cognitive responding and attitude change. It should be noted, however, that these procedures do not *prove* that a particular causal model is operating. These analyses were conducted here to assess if the reduced agreement found with increasing discrepancy possibly resulted from counterargumentation. Pre-

Within-cell correlations further revealed that unfavorable thoughts were positively correlated with ratings of effort ($r = .42$, $p < .05$), involvement ($r = .43$, $p < .05$), and responsibility ($r = .29$, $p < .05$), and correlated negatively with ratings of distraction ($r = -.29$, $p < .05$). None of the electrophysiological measures was correlated significantly with any ancillary measure.

In sum, electrophysiological and thought-listing measures indicated that topic-relevant cognitive responding accompanied the anticipation of an involving counterattitudinal communication. Inspection of Figure 1 supports the notion that cognitive response processes in persuasion can be measured concurrently and without the subject's doing anything overt in particular (e.g., listing thoughts). Of course, no evidence was provided in Experiment 1 concerning the natural existence or elicitation of cognitive response in persuasion, since the subjects were aware that they were to list their thoughts; in fact, they had been instructed to collect their thoughts following each forewarning. We were also unable to distinguish electrophysiologically the affective natures of the recipients' covert preparations for the advocacy. We conducted a second experiment to address these issues.

Experiment 2

The first issue, that of providing electrophysiological evidence concerning the cognitive responses elicited naturally in persuasion, was addressed easily in the design of Experiment 2. Rather than asking the subjects to collect or list thoughts, we simply monitored the electrophysiological activity displayed during the anticipation and presentation of a single advocacy. Subjects had no notion that they would subsequently be asked to list their thoughts.

The second issue, developing an electrophysiological measure capable of differentiating the affective nature of cognitive responding (should it exist in persuasion), proved to be more difficult. Previous studies of attitudes and bodily reactions have employed three basic research strategies: Procedures have been employed (a) to tap the physiological processes indicating covert information processing (e.g., Experiment 1; Cacioppo, 1979); (b) to measure an evaluative reaction by monitoring a classically conditioned physiological response (e.g., Tognacci & Cook, 1975); and (c) to assess the naturally occurring physiological indicators of affective states (e.g., Cooper, 1959; Hess, 1965). Studies of attitudes applying the third research strategy have often used measures of pupillary response or electrodermal activity (galvanic skin responses). These studies have provided some evidence that attitudes, if extreme, may be measurable. Even in these instances, however, the polarity of the attitude (i.e., positive or negative) has not been distinguishable (Cacioppo & Sandman, in press; Mueller, 1970).

Recent work on the neuromuscular substrates of emotion and depression offered us a potential solution. Darwin (1965/1872) first documented the specificity and reliability of facial muscle patterning in the expression of emotions (cf. Cacioppo & Petty, in press-a). More recently, Schwartz and his colleagues (Schwartz, 1975; Schwartz et al., 1976a, 1976b) have found that generating

---

...iously we have found that topic-relevant thinking ...ppears to mediate the subsequent agreement with ...e advocacy (Cacioppo & Petty, 1979; Petty & ...acioppo, 1977), rather than vice versa. We expected ...e same results from the present study. (See Insko ...t al., 1974, for an extended rationale for the use of ...nalyses of covariance [ANCOVA] with attitude and ...gnitive response measures.)

A series of analyses of covariance were performed ...h which agreement served as the criterion and each ...gnitive response (one per analysis) served as the ...variate. A second series of covariance analyses was ...erformed in which agreement served as the covariate ...d each cognitive response served as the criterion. ...e results of these analyses revealed only that the ...variate, counterarguments, reduced the overall F ...tio for the discrepancy factor for agreement: the ...F statistic for agreement was reduced from a signif... ...ast 3.57 to a nonsignificant 1.70 ($df = 2, 41$). The ...alysis of covariance with counterarguments as the ...iterion and agreement as the covariate did not ...minate the significant F ratio for counterarguments, ...COVA $F(2, 41) = 5.53$. These analyses are consistent ...th the notion that increasing discrepancy increased ...unterargumentation, which then reduced agree-...ent.

imagery or attempting to experience through fantasy the emotional states of happiness, sadness, and anger leads to distinctive patterns of EMG activation of the face. Moreover, these patterns go unnoticed by subjects as well as observers (see also Izard, 1971). We reasoned that by monitoring these facial (i.e., corrugator, zygomatic, depressor anguli-oris, and mentalis) muscles during the anticipation and presentation of advocacies, we would be able to distinguish favorable from unfavorable (i.e., counterargument) cognitive responses emitted by a recipient. In Experiment 1 and in previous research, we have found oral EMG to distinguish the extent rather than the affectivity of covert processing (e.g., Cacioppo & Petty, in press-b, in press-c). Hence, we considered the measure of mentalis EMG activity, which taps the electrical activity of the muscle fibers between and including the lower lip and chin, as a measure of the extent rather than emotionality of processing (see also McGuigan, 1978). Again, heart rate was recorded.

Method

Subjects and Design

Sixty male undergraduates were led to believe they were evaluating the sound quality of taped radio editorials that had been produced by the students in a sound-engineering course. Electrodes were placed on each subject's body, and subjects were tested individually in a darkened, sound-attenuated room "to reduce external distractions from the task." Forty-eight subjects were forewarned about and heard either a proattitudinal or a counterattitudinal advocacy on one of two topics (alcoholic beverages or visitation hours). Twelve additional subjects were forewarned only that they would hear a taped communication, and they heard a message about an obscure news event. Subjects in this group served in an external control (neutral advocacy) condition. The assignment of subjects to condition again was determined randomly.[8]

Materials

The topics of alcoholic beverages and visitation hours were selected because initial pilot testing revealed existing university regulations regarding them to be highly involving and counterattitudinal. Forewarnings and messages were constructed that advocated the adoption of either stricter (counterattitudinal) or more lenient (proattitudinal) regulations regarding these issues. The neutral message concerned a small archeological find and was obtained from a past issue of a national news magazine.

Procedure

When subjects arrived at the laboratory, they were told that their task was to evaluate the sound quality of a taped radio editorial, that electrodes would be attached, and that during the study we would be recording the involuntary bodily responses that accompany listening to a communication.[9] Subjects were instructed to refrain from unnecessary movements, to breathe normally, and to keep their eyes closed throughout the study. After adapting to the laboratory, subjects again heard these instructions and were told that the study would begin shortly. At this point, a computer-controlled procedure—which involved (a) a 60-sec prewarning (baseline) interval, (b) a 15-sec forewarning, (c) a 60-sec postwarning–premessage interval, and (d) a 120-sec message—was initiated.

After listening to the tape, the subjects read the following:

> Because your own opinion about the position advocated on the tape may influence the way you rate the quality of the tape, we would like to obtain a measure of how you feel about the views proposed by the speaker on each scale below.

The subjects responded to four 9-point semantic differentials; their responses were summed to obtain a measure of their attitude toward the advocacy. In the same manner as in Experiment 1, subjects were instructed to list everything about which they had thought during the message (subjects were given 3 minutes). Afterwards, subjects rated their listed thoughts as favorable (+), unfavorable (−), or neutral/irrelevant (0) toward the message. Subjects then rated on 11-point Likert-type scales their felt involvement, effort, and distraction, the personal relevance of the message, the sound quality of the tape, and the speaker's rate of delivery and enthusiasm.

Heart rate. Grass E5S cup electrodes filled with Grass EC3 paste were placed over the lower left rib and the right collar bone. The signal was amplified

---

[8] An additional factor included in the design was whether subjects were informed that the communication had implications locally or not. Manipulation checks revealed that our manipulation of this factor failed here, so this factor is not discussed further.

[9] Electroencephalographic measures were obtained also, the results of which are to be reported elsewhere, since they were collected to address a different issue. Suffice it to say that enough electrodes were attached to subjects to make the cover story concerning the measurement of involuntary processes seem entirely plausible to them.

by a Narco Biosystem Physiograph AC preamplifier. The output was displayed on a Narco Biosystem Physiograph 6 and was transmitted on-line to a PDP-8I laboratory computer for analysis.

Facial muscle activity. Grass E5S cup electrodes filled with Grass EC3 paste were placed adjacent to each other in pairs with interelectrode resistance reduced to less than 10,000 ohms. The four muscles over which the pairs of electrodes were placed were the corrugator (just above the eyebrow), zygomatic (upper cheek), depressor anguli oris (lower cheek), and mentalis (between lip and chin) on the left side of the face (cf. Schwartz et al., 1976a). Since surface electrodes were used, recordings of EMG activity were obtained from these and surrounding muscle groups.

Each EMG measure was amplified by a Narco Biosystem Physiograph AC preamplifier, individually rectified and summed by an EMG integrator with a time constant of .2 sec. The average integrated EMG was displayed on the physiograph with a full-scale pen deflection of 40 mm (1 mm = 7.5 μV). The integrated EMG also was transmitted on-line to the PDP-8I laboratory computer, sampled 10 times per second, and recorded. The computer was programmed to eliminate from its recordings any obvious movement artifact or overt (e.g., visually detectable) facial expression.

Data reduction. The cognitive data were scored in the same manner as in Experiment 1. Physiological responses were monitored during the minute preceding the forewarning through the completion of the 120-sec message. The data for each measure were averaged for each subject and each interval. Difference scores relative to the prewarning (basal) levels were calculated for each measure and interval, and nonparametric analyses were employed, since the data were not distributed normally. The presentation here of the results for facial EMG activity is similar in format to the presentation by Schwartz et al. (1976a, 1976b) to facilitate comparisons.

Results and Discussion

Our purposes in this study were to determine if cognitive responses were generated naturally in persuasion settings and, if so, whether or not the *affective nature* of these responses could be assessed electrophysiologically. A multivariate analysis of variance of the 11 questionnaire measures was conducted first to determine the general effects of the experimental factors. As expected, the effect of position was highly significant, based on Wilks' lambda, $F(11, 30) = 3.63$, $p < .01$, and the effect of topic was not significant, $F(11, 30) = 1.74$, $p > .11$. Hence, all analyses reported below are collapsed across the topic factor.

Table 3
Mean Cognitive and Attitudinal Responses as a Function of the Affectivity of the Advocacy: Experiment 2

Measure	Pro-attitudinal	Counter-attitudinal	Neutral
Evaluation of the taped advocacy	27.04	16.75[a]	25.00
Counterarguments	2.00	3.54	2.17
Favorable thoughts	2.34[a]	1.13	1.25
Neutral/irrelevant thoughts	2.04	1.54[a]	3.33
Total thoughts	6.38	6.23	6.74

[a] The mean differs from the corresponding neutral mean at the .05 level by Dunnett's test.

Cognitive Response, Attitude, and Ancillary Measures

Subjects anticipated and listened to a proattitudinal advocacy, a counterattitudinal advocacy, or a neutral communication, and rated their evaluation of and thoughts about the taped presentation. As is evident from an inspection of the means in Table 3 for these measures, the proattitudinal advocacy was evaluated more positively, $F(1, 40) = 30.37$, $p < .001$, and elicited more favorable thoughts, $F(1, 40) = 6.58$, $p < .02$, and fewer counterarguments, $F(1, 40) = 6.50$, $p < .02$, than did the counterattitudinal advocacy.

The Dunnett test for comparisons involving an external control mean (Kirk, 1968) was employed to determine the relative effects of the proattitudinal and counterattitudinal communications relative to the neutral communication on cognitive and attitudinal responding. These comparisons revealed that the neutral communication differed from the counterattitudinal communication in evaluation and in the number of neutral/irrelevant thoughts elicited (ps $< .05$); in addition, these communications differed marginally in the number of counterarguments elicited ($p < .10$). On the other hand, the neutral and proattitudinal communications were evaluated and were thought about similarly (see Table 3). Evidently the subjects enjoyed hearing our "neutral" message about an archeological dig.

Analyses of the ancillary measures and ratings of tape quality failed to produce any significant effects.

Electrophysiological Measures

All tests of the significance of changes from prewarning baselines for the electrophysiological measures were conducted using two-tailed Mann-Whitney tests.

Does cognitive responding occur naturally? The analyses of covert oral (mentalis) EMG activity, which was the most sensitive measure of covert processing in Experiment 1, indicated that it was elevated during the postwarning–premessage interval for the *counterattitudinal* condition ($Mdn = .24$ μV, $p < .03$). This finding replicates that of Experiment 1, but here was obtained without explicit requests for subjects to collect their thoughts. Interestingly, oral EMG activity was *not* altered significantly during this interval in the proattitudinal or neutral conditions ($ps > .15$). Still, the *presentation* of a message, whether it was proattitudinal, counterattitudinal, or neutral, led to increased oral EMG activity ($Mdn = .43$ μV, 1.21 μV, and 1.26 μV, respectively, $ps < .03$). Also, as in Experiment 1, the affective nature of the covert processing was not distinguishable by oral EMG; the mentalis activity did not differ as a function of position. The analyses of heart rate indicated that this measure was less sensitive than oral EMG activity, as differences from basal levels were evident only during the presentation of the communications (counterattitudinal $Mdn = .73$ bpm; proattitudinal $Mdn = .36$ bpm; neutral $Mdn = 2.68$ bpm; $ps < .05$). Finally, changes in heart rate during the communication were greater for the neutral than for the counterattitudinal ($p < .03$) and the proattitudinal ($p < .04$) conditions. The cause of this difference is not immediately apparent, but the news story about the archeological find may have required more thought to comprehend or elaborate, producing greater accelerations of heart rate.

Is the emotional tone of this cognitive activity distinguishable? We next sought to determine if the affective nature of the cognitive responses was distinguishable by the pattern of *facial* EMG activity. Schwartz and his associates have demonstrated that pleasant states (e.g., happiness) lead to less corrugator and more zygomatic and depressor EMG activity than do unpleasant states (e.g., sadness, anger), with corrugator EMG activity providing the most discriminating measure (Schwartz, Fair, Salt, Mandel, Mieske, & Klerman, 1978). Figure 2 displays the median change from baseline for these measures as a function of position and interval in the present study.

Several findings are evident immediately upon inspection of Figure 2. First, only corrugator activity was altered during the announcement of the *forewarning* (upper panel), with greater and equal activation relative to baseline appearing in all conditions ($ps < .01$). Less evident in the upper panel of Figure 2 is the marginally significant tendency for zygomatic activity to discriminate between the counterattitudinal and neutral forewarnings ($p < .06$).

During the *postwarning–premessage* interval (middle panel of Figure 2), corrugator activity remained elevated from basal levels ($ps < .02$), though a significant decrease from the forewarning level was displayed in the proattitudinal condition ($p < .01$). Between-group comparisons yielded a nonsignificant difference in corrugator activity between the proattitudinal and counterattitudinal conditions ($p < .11$), with the direction of the difference that which would be expected from Schwartz and his colleagues' research. That is, corrugator activity was higher when anticipating the counter than proattitudinal advocacy. Finally, the activity in the zygomatic muscle region in the neutral condition was enhanced relative to basal levels ($p < .03$) and distinguished this condition from the group anticipating a counterattitudinal advocacy ($p < .01$). This too is consistent with the previous studies of emotional fantasy and imagery (cf. Schwartz, 1975). No other differences were statistically significant.

The *presentation* of the messages (lower panel of Figure 2) resulted in elevated corrugator EMG activity relative to basal ($ps < .01$) and postwarning–premessage levels (ps

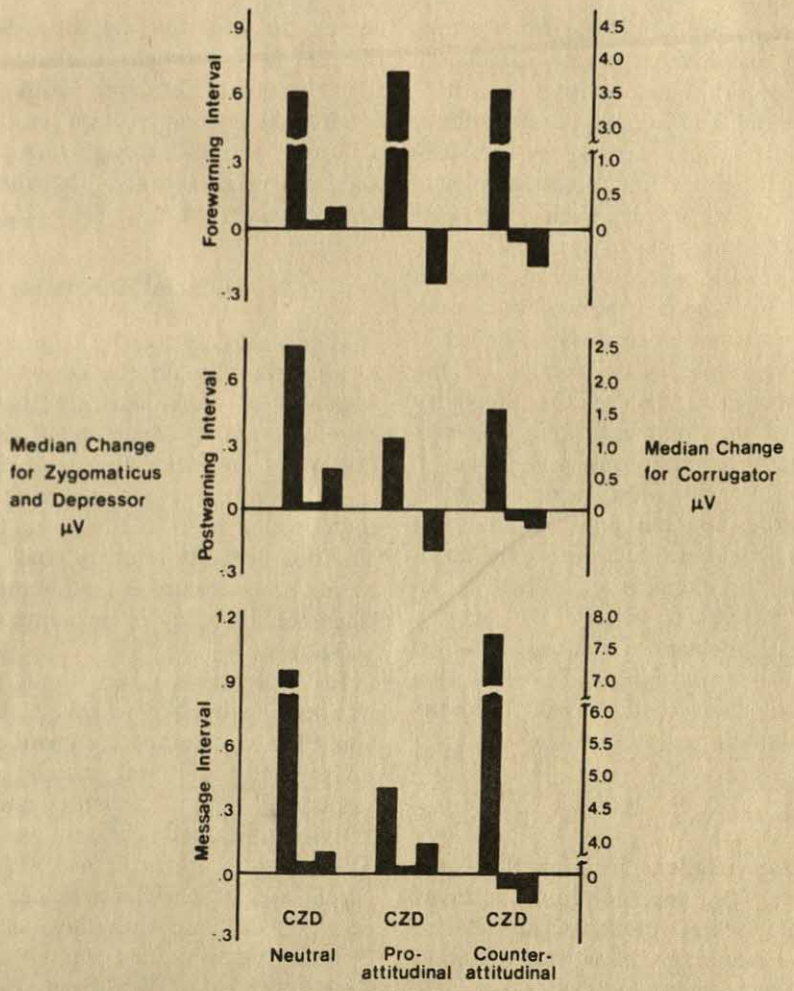

Figure 2. Median change from baseline for corrugatory (C), zygomaticus (Z), and depressor (D) electromyographic activity during the forewarning (top panel), postwarning-premessage (middle panel), and message (bottom panel) intervals. (The data are displayed separately for subjects who anticipated and heard the neutral [$n = 12$], proattitudinal [$n = 24$], and counterattitudinal [$n = 24$] advocacies.)

< .01); in addition, it was elevated marginally during this interval compared to forewarning levels (ps < .06). The zygomatic activity continued to differentiate the affectivity of the covert processing: Zygomatic EMG activity during the counterattitudinal message was lower than that displayed during baseline ($p < .05$), the proattitudinal message ($p < .01$), and the neutral message ($p <$ .05). Furthermore, the zygomatic activity during the proattitudinal message was significantly greater than its basal level and marginally greater than its forewarning ($p <$ .08) and postwarning–premessage levels ($p <$ .08). Similarly, depressor EMG activity was enhanced marginally during the proattitudinal message compared to its postwarning–premessage level ($p < .06$) and compared to the counterattitudinal message ($p < .10$), effects also similar to those found by Schwartz et al. (1976a, 1976b). No other comparisons approached statistical significance.

In sum, oral EMG activity increased from baseline after the forewarning of an impending and involving *counterattitudinal* communication, even though we did not request subjects to collect their thoughts and subjects were unaware that they would be asked to list

their thoughts, heard only one forewarning and message, and had no reason to suspect the purpose of our measurements. Furthermore, anticipating and hearing proattitudinal, counterattitudinal, and neutral communications led to distinctive and predictable patterns of facial EMG activity during the stimulus sequence. Specifically, less corrugator and more zygomatic activity was observed in the proattitudinal and neutral conditions than in the counterattitudinal condition. The activity of the depressor muscle region, for the most part, was unaffected by the affectivity or interval of the communication sequence. The differences that *were* observed, however, were as predicted: Depressor activity tended to be greater during the proattitudinal and neutral communications than during the counterattitudinal communication. Finally, although the patterns of facial EMG activity were similar for the neutral and proattitudinal conditions, there was a high degree of similarity between these conditions in the cognitive and evaluative responses as well.

Correlational Analyses

Canonical correlations between the cognitive responses (i.e., counterarguments, favorable thoughts, neutral thoughts) and electrophysiological scores (i.e., heart rate, mentalis, corrugator, zygomatic, and depression EMG activity) were calculated, once using the physiological responses for the postwarning–premessage interval, and once using the responses for the message interval. Since thought listings were obtained immediately following the message interval, the canonical correlation between thoughts and the bodily responses from this interval should show the strongest association; but physiological responses from both intervals should correlate somewhat with the listed thoughts. Correlations were .30 for the postwarning–premessage interval and .46 for the message interval, $\chi^2(15) = 7.20$ and 16.20, respectively, *ns*. Hence, the covariation of cognitive and electrophysiological response was weak by these indices, but the latter index was stronger than the former, as expected.

Calculations of within-cell correlations among the cognitive response data revealed that, as in Experiment 1, counterargumentation correlated negatively with the attitude toward the communication ($r = -.30$, $p < .05$) and favorable thoughts ($r = -.41$, $p < .05$), whereas favorable thoughts correlated positively with attitude ($r = .45$, $p < .05$).

General Discussion

Theory and research in persuasion have focused recently on the covert idiosyncratic responses of individuals. In this article, we have reported two experiments describing the theory for and development of electrophysiological procedures for assessing this covert cognitive activity. Moreover, the evidence obtained suggests strongly that cognitive response processes are evoked naturally, at least when the advocacy is involving and counterattitudinal.

In Experiment 1, we found that subjects who had been asked to collect their thoughts about an upcoming discrepant message exhibited increased oral muscle, cardiac, and respiratory activity, whereas nonoral somatic activity remained constant and quiescent. These results are in accord with research in cardiovascular psychophysiology (e.g., Lacey et al., 1963) and with the literature on the electromyographic concomitants of thought (Jacobsen, 1973; McGuigan, 1978; Sokolov, 1972). Further, these results demonstrate that cognitive responses in persuasion settings are measurable concurrently and reliably, without asking the subject to respond overtly during the measurement and without the subject's awareness of the purpose or focus of the (electrophysiological) measurement instruments.

A second experiment was conducted to provide answers to two important questions: (a) Do subjects engage normally in active, covert processing when anticipating and hearing persuasive appeals? (b) If so, can the emotional tone of this cognitive activity be assessed electrophysiologically? Using an electromyographic technique to measure subtle responses of the facial muscles, we found that the forewarning of a counterattitudinal, but not a proattitudinal or neutral, communication

led to elevated oral EMG activity. Furthermore, the anticipation and presentation of counterattitudinal, proattitudinal, and neutral communications led to active though covert processing activity, the affective nature of which was revealed in the concomitant patterning of facial EMG activity.[10]

Cognitive Encoding or Elaboration?

It might be argued that the increased oral muscle activity indexed silent rehearsals rather than cognitive elaborations of the message arguments (cf. Miller & Baron, 1973). Listening to prose does cause a slight increase in oral muscle activity (McGuigan & Bailey, 1969a). Hence, comprehending and rehearsing the message arguments probably contributed to the elevated oral muscle activity exhibited *during the message presentation*. However, the *anticipation* of a counterattitudinal advocacy led to elevated speech muscle activity when there were no message arguments to rehearse. One might argue that subjects were rehearsing the forewarning and potential message arguments, stopping to generate counterarguments only when asked by the experimenter at the end of the study to "list everything about which you thought." Besides the absence of parsimony, this explanation fails to account for the subtle facial expressions indicating affect-laden cognitive responding that was displayed while subjects awaited the message. More persuasively, this explanation cannot account for the failure of subjects who were expecting a proattitudinal message to display significant increases in oral muscle activity during the postwarning–premessage interval.

Cognitive, Attitudinal, and Electrophysiological Response

According to the cognitive response analysis, a forewarning of an upcoming and involving discrepant communication elicits preparatory cognitive activity (e.g., anticipatory counterargumentation) in an effort to rally one's cognitive defenses (Cialdini et al., 1976; McGuire & Papageorgis, 1962; Petty & Cacioppo, 1977). Interestingly, there are no studies in the literature that report the effects of anticipating a proattitudinal message that collected thought listings. We believe that anticipating a counterattitudinal as compared to a proattitudinal message generally results in deeper processing (i.e., more extensive cognitive preparation—Cacioppo & Petty, 1979). This difference may be attributable to the relative importance in defending from attack one's attitudes and beliefs (e.g., avoiding cognitive inconsistency), or to the relative thought that was devoted previously to (or scripts developed for) proattitudinal rather than counterattitudinal positions. The present study does not consider which of these interpretations is most plausible.

It should be noted that the observation of greater oral EMG activity being obtained when anticipating a counterattitudinal rather than proattitudinal or neutral communication does *not* imply that oral EMG activity is a measure of "counterargumentation." Indeed, the results of both experiments suggest it is not. As mentioned above, we believe that the cognitive preparation for a counterattitudinal rather than a proattitudinal or neutral message elicits more extensive processing, which may result in the generation of counterarguments, favorable thoughts, *and/or* neutral thoughts. Accordingly, the activation of the oral muscles reflects this difference in the extent of cognitive elaboration rather than the affectivity of the processing. Evidence that oral EMG reflects this depth of processing has been found in a study in which subjects viewed a word and identified whether it was printed in uppercase letters (shallow processing) or was self-descriptive (deep processing —Cacioppo & Petty, in press-b, in press-c). We found that deeper processing resulted in elevated speech EMG activity.

Finally, a word might be said about the

---

[10] Love (1972) attempted to detect subtle changes in facial expression by videotaping the shoulders and face of subjects as they listened to an advocacy. Raters then scored the nonverbal cues emitted by these subjects. This measure proved to be insensitive to the experimental manipulations. The electrophysiological approach illustrated here has the advantage of being sensitive to subtle changes in responding by recipients.

sensitivity and specificity of the electrophysiological measures employed. The procedures we employed for scoring these responses eliminated obvious movement artifacts and facial expressions (the number of the edits did not differ across the experimental conditions); hence, we intentionally confined ourselves to the study of covert electrophysiological responses. Nevertheless, in this research, oral EMG activity has been a more sensitive measure of covert information processing than heart rate (see also McGuigan, 1978). Heart rate and speech muscle activity increased following the forewarning of an upcoming discrepant message, but the change in heart rate in Experiment 2 was not significant statistically; heart rate *did* increase significantly during the presentation of the communications, although again, the electromyographic measures proved more sensitive. Similarly, the various measures of facial EMG activity were not equally sensitive to affect-laden processing. Schwartz and his colleagues (1976a, 1976b, 1978) have found, as we here have found, that corrugator EMG activity best distinguishes subtle affective states. These instances of differing sensitivity, or response discordance, illustrate a point made by the Laceys (e.g., 1959, 1967) regarding the specificity of autonomic and somatic activation. Moreover, this remarkable specificity contrasts sharply with Cannon's (1927) theory of physiological arousal and emotion, and provides unique evidence for cognitive response processes in persuasion.

Instructions for Submission of Manuscripts

Papers submitted to the *Journal of Personality and Social Psychology* after April 1, 1979 will be considered under new policies approved by the Publications and Communications Board. Effective with the 1980 volume of the journal, the following policies will apply:

The *Journal of Personality and Social Psychology* publishes original papers in all areas of personality and social psychology. It emphasizes empirical reports but may include specialized theoretical, methodological, and review papers. Beginning in April 1980, the journal will be divided into 3 independently edited sections: ATTITUDES AND SOCIAL COGNITION, INTERPERSONAL RELATIONS AND GROUP PROCESSES, and PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES. Authors should submit manuscripts to the appropriate section editor according to the section definitions and manuscript preparation instructions provided on page 468 of the March 1979 issue of the journal.

Section editors' addresses are as follows: ATTITUDES AND SOCIAL COGNITION, Melvin Manis, Editor, Research Center for Group Dynamics, Institute for Social Research, University of Michigan, Ann Arbor, Michigan 48106; INTERPERSONAL RELATIONS AND GROUP PROCESSES, Ivan D. Steiner, Editor, Department of Psychology, University of Massachusetts, Amherst, Massachusetts 01003; PERSONALITY PROCESSES AND INDIVIDUAL DIFFERENCES, Robert Hogan, Editor, Johns Hopkins University, Department of Psychology, 33rd and Charles Streets, Baltimore, Maryland 21218.

Remembering Schema-Consistent Information: Effects of a Balance Schema on Recognition Memory

Keith P. Sentis and Eugene Burnstein
University of Michigan

The major premise of this article is that schema-consistent (balanced) information is structurally represented in memory in a qualitatively different fashion from schema-inconsistent (imbalanced) material. The former closely resembles overlearned information and "easily chunked" information in that multicomponent stimuli are represented in memory as unitary wholes, whereas the latter is stored as discrete propositions. Subjects studied short scenarios that described either balanced or imbalanced structures involving three relations and then answered questions that required retrieval of either one, two, or all three of the relationships. For imbalanced information, reaction times to questions increased with the number of to-be-retrieved relations, whereas with balanced information, reaction times actually *decreased* as the number of to-be-retrieved relationships increased. Thus, for balanced structures, all three relations were more quickly verified than any two, and any two were more quickly verified than any one. A model is proposed for the operation of the balance schema that explains why the whole is retrieved more easily than its parts.

During at least the past 100 years, there has been a sustained belief that the concept of *knowledge structures* is useful for explaining mental processes. This is evident in the remarkable similarity between the descriptions of cognitive organization contained in the works of several nineteenth-century theorists and those offered by current researchers in cognitive psychology and artificial intelligence. To cite only one example, regarding cognitive representations of frequently repeated episodes, Butler (1877) felt that "the memory of many past performances strikes a sort of fused balance in the mind, which results in a general method of procedure with but little conscious memory of even the latest performances, and with none whatever of by far the greater number of the remoter ones" (p. 158). A recent iteration of Butler's ideas can be found in Schank and Abelson (1977), who note that "as an economy measure in the storage of episodes, when enough of them are alike they are remembered in terms of a standardized generalized episode which we will call a script . . . This economy of storage has a side effect of poor memory for detail" (p. 19).

The research presented here is concerned with knowledge structures pertaining to the social environment, that is, *social schemas*. Social schemas are coherent conceptual frameworks for representing relationships among social stimuli that guide the individual in organizing the social world. These cognitive structures are built up on the basis of experience with social reality and are active in the interpretation and comprehension of novel social events. In particular, we will focus on schemas about social relationships that can

Portions of these data were reported at the American Psychological Association meeting, San Francisco, August 1977. This research was supported in part by Grant MH29140-02 from the National Institute for Mental Health. We are indebted to Roberta Klatzky and Hazel Markus for their valuable advice and commentary throughout all phases of this research. We also thank Michael Siladi for his assistance with the data analysis, as well as Ruth Hamill, Stephen Slade, and Ed Smith for their comments on an earlier version of this article.

be described in terms of structural balance. Heider (1958) postulated that social relations, to the extent that they form a balanced structure, are subject to Gestaltlike organizational principles in that balanced relations are perceived as a cohesive unit, whereas imbalanced relations are not—the latter, in fact, are thought to be disharmonious and cognitively segregated (Heider, 1946).

Naturally, a schema about relations between people should influence the processing of social information. Indeed, one of Heider's important hypotheses was that information consistent with a balance schema will be better remembered than information inconsistent with the schema (1958, p. 184). Prior investigations of this hypothesis have employed a variety of procedures, including paired associates learning (Zajonc & Burnstein, 1965a, 1965b; Zajonc & Sherman, 1967) and conceptual rule learning (Cottrell, 1975), as well as recall (Gerard & Fleischer, 1967) and recognition tasks (Delia & Crockett, 1973; Sherman & Wolosin, 1973). The results, however, have provided only checkered support, with contradictory findings occurring not only across but also within methodologies.

The present inquiry into the nature of the balance schema, especially its effects on memory, uses chronometric procedures that are standard in the study of information processing but are relatively novel in the area of social schemas. Substantively, it is concerned with how the balance schema functions. This issue was most recently explored by Picek, Sherman, and Shiffrin (1975). They had subjects indicate whether the relationships between people in stories they had read earlier were positive or negative or were not presented. Fewer errors were observed on the balanced stories than on the imbalanced ones. Moreover, there was a distinctive effect of the order in which the relationships were presented, with the most errors occurring on the third and succeeding relationships in the imbalanced structures—the point in the narrative at which the social situations became unambiguously imbalanced (or balanced). These findings suggest that once the degree of balance of a social structure could be determined, the balance schema resulted in schema-consistent information being stored in a simpler and more available manner than is schema-inconsistent information. As a result, subjects were able to retrieve the former more easily from memory. The critical question, which remains open, is *how* does it come about that schema-consistent information is stored more efficiently and hence is more easily retrieved than schema-inconsistent information.

Retrieval processes have been extensively investigated using a paradigm in which subjects study several sentences, are later presented with a probe sentence, and are asked to decide whether they have seen it before (e.g., Anderson, 1976; Anderson & Bower, 1973). Some of the discoveries using this procedure are important for our analysis of social schemas, in particular the finding that the more facts learned about a particular concept, the longer it takes to recognize correctly a relevant sentence as having appeared before ("old") or as not having appeared before ("new"). The relationship between the number of sentences learned about a concept and sentence recognition time has been termed the "fanning effect." This name derives from the memory model used in this research, which postulates that the concept becomes a central node in a memory network and that facts about the concept are linked to this central node. These facts are thought to "fan out" from the concept node. As their number increases, the number of network paths to be searched in the recognition process also increases, and therefore the more time-consuming the search process. As a consequence, the more that is known about a concept, the longer it takes to correctly recognize any sentence about that concept.

The counterintuitive implications of the fanning effect are that an increase in knowledge about a topic hinders our ability to answer questions about the topic readily or that an expert will answer questions more slowly than a novice. The fanning effect thus poses a paradox. How can someone with expertise on a certain topic answer questions about the topic more readily than a less knowledgeable person, despite having to search through a much larger data base of

relevant information? One class of explanations for this paradox centers on the frequency with which the facts are retrieved. Hayes-Roth (1977), for instance, has shown that the fanning effect disappeared after extended practice with the same set of facts. More relevant to our purpose, however, is the work by Smith, Adams, and Schorr (1978), who were interested in how the retrieval interference represented by the fanning effect could be overcome when the facts involved have *not* been frequently retrieved. They observed that when subjects learned sets of facts that could be *combined as a meaningful unit* by reference to knowledge about the world, the fanning effect was eliminated. These findings imply that information that can be *integrated* is more easily retrieved than information that cannot be integrated. Recall that a central theme in Heider's analysis of social perception is that balanced social relationships form a Gestalt, that is, they tend to be represented as integrated wholes or units. Imbalanced relations, on the other hand, are postulated to be cognitively segregated. If this is true, it would seem to follow from the research on the fanning effect by Smith et al. that balanced relationships are retrieved with relative ease *because* the balance schema allows for a highly integrated representation in memory of schema-consistent information. This means that the schema serves as a mapping function and generates an integrated memory representation of the individual components of information that are consistent with it. More specifically, such an analysis implies that (a) the balance schema integrates information consistent with the schema, which (b) results in less retrieval interference for balanced relationships than for imbalanced ones; consequently, (c) memory for balanced structures is relatively superior. As mentioned earlier, Smith et al. (1978) showed that integration of facts offset retrieval interference and reduced recognition times. If balanced information is stored in memory in a more integrated fashion than imbalanced information (and hence is more easily retrievable), this should be reflected in lower reaction times (RTs) for questions about the balanced structures than for questions about imbalanced structures.

In essence, we propose that balanced social relationships are represented in memory in a fundamentally different fashion from imbalanced relationships. We investigated the structural differences in the representation of balanced and imbalanced information by using a technique originated by Sternberg (1966, 1969, 1974), whereby subjects memorize a set of items and then respond to a test item by indicating whether or not the latter is a member of the memorized set. If RT increases as a function of size of the memory set, this indicates a *serial comparison* between the probe stimulus and the memory set items. However, if RT does not increase with memory set size, then *parallel comparisons* would be indicated.[1] In the former case, a positive slope for the RT function with respect to set size is a sensitive index of the time it takes for each comparison. Furthermore, the scanning of the memory set in an item-by-item fashion implies that the components of the memory set are represented as discrete units in memory. In contrast, an RT function with no slope would mean that the several items could be processed as rapidly as one. This parallel processing would indicate that the components of the memory set are stored as an integrated representation such that the items are available for comparison all at once (Hayes-Roth, 1977). Variations of Sternberg's technique have been used to investigate the issue of integration of visual images. For example, De Rosa and Tkacz (1976) found no effect of set size on RT in a Sternberg task when the material in the memory set could be integrated into a single representation. Similar results were obtained by Guenther (Note 1) using cartoonlike pictorial stimuli and by Salthouse (1977) using

[1] As discussed by Townsend (1972), a positive RT slope would also be indicative of a limited capacity parallel process. In addition, Anderson (1976) demonstrated that a serial model can make equivalent predictions to any parallel model. However, in many instances, the equivalent serial (or parallel) model must incorporate some rather nonintuitive assumptions. Thus, for our purposes, the original distinction will suffice.

dot pattern prototypes. Finally, Thompson and Klatzky (1978) suggest that Gestaltlike organizational principles are used to encode visual stimuli and that under certain conditions these principles facilitate parallel, unlimited capacity processing.

The present research on the balance schema used a variant of the Sternberg technique to evaluate the hypothesis that information consistent with a balance schema is represented in memory as an integrated unit. In this study, subjects studied two scenarios describing P-O-X triads (i.e., social structures comprised of the affective relationships between two people and their attitudes toward an issue). One scenario described a balanced structure, the other an imbalanced one. Following the study session, subjects answered questions about these scenarios that required them to verify one, two, or all three of the relationships in the structure. Notice that in our version of the Sternberg task, the size of the memory set is constant and the size of the probe (i.e., the size of the retrieval set) is varied. We expected that the slope of RT as a function of the number of structural relationships to be verified should reflect the integrative function of the balance schema. This means that if the balance schema results in subjects forming an integrated representation of the scenarios, then the RT function ought to reflect differences in the degree to which this integration occurred. Specifically, as the degree of integration increases, the slope of RT as a function of the size of the retrieval set should decrease. We predict, therefore, that because schema-consistent information is more readily integrated than schema-inconsistent information, the former should exhibit a flat slope and the latter a positive slope for the function relating RT to the number of relationships to be verified in the question.

Method

Subjects

Subjects were 38 undergraduates enrolled in introductory psychology classes. The 35 males and 3 females received course credit for their participation. Data from six subjects who made more than six errors during the 56 trials were excluded from the analyses.

Materials

Scenarios. Two short descriptions of hypothetical stuations were used, each involving two persons of the same sex and an issue. Each of the scenarios was five sentences long and contained the following information: (a) brief description of both individuals, (b) the interpersonal sentiment relationship between the individuals, (c) the relationship between the persons and the issue, that is, their attitudes toward the issue.

Two versions of each scenario were generated by reversing the relationships between the entities. This reversal of relationships produced one version in a balanced state and the other in an imbalanced one. Two sets of scenarios were formed by varying the order of occurrence of the balanced scenario. Approximately equal numbers of subjects were randomly assigned to each set of scenarios. In both sets, the scenario about admissions quotas preceded the abortion scenario. In the two scenarios that are reproduced below, the reversed relationships that appear in parentheses were substituted for the preceding italicized sections to produce imbalanced versions of the scenarios.

Scenario 1. Mary has been married for three years and has a year-old child. She is very much *opposed to* (in favor of) liberal abortion legislation and works on a local committee that is lobbying *against* (for) such legislation. Susan strongly *opposes* (favors) liberal abortion laws and is one of the most active members of the local committee. Mary and Susan became acquainted through their work together on the committee. They have grown to *like* (dislike) each other very much.

Scenario 2. Bill is a senior at a large university and has majored in Sociology. Bill is applying to several prestigious law schools and strongly *opposes* (favors) the graduate schools' admissions policy that is based on racial quotas. John is also a senior at the same university and he is an Urban Studies major. John is applying to these law schools also and is very much *opposed to* (in favor of) the quota system. Bill and John *are* (are not) friends; in fact, they *like* (dislike) each other very much.

Questions. Fourteen distinct questions were constructed about each scenario (28 in all). Since we were interested in analyzing RT as a function of the complexity of the question, the questions were presented in a schematic format rather than in verbal form, in an attempt to minimize differences in question encoding times. Each schematic question took the form of three words from the scenario (two names and an issue) and from one to three symbols (+ or −), used to represent the relationships between the entities in the scenarios. Typical schematic questions are shown in Figure 1. The spatial arrangement of the words and symbols was constant across questions. Subjects were required to verify the rela-

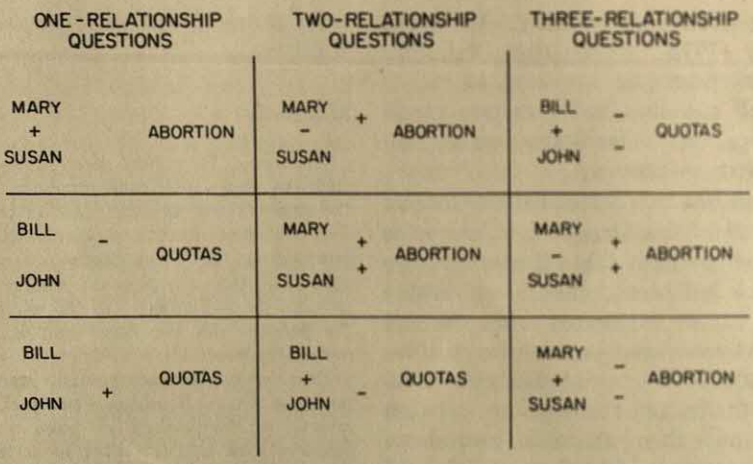

Figure 1. Examples of schematic questions presented to subjects.

tionships represented by the symbol(s) in the schematic question against the corresponding relationship(s) in the scenario by responding *true* or *false* to each question.

The 14 schematic questions about each scenario formed three sets, according to the number of relationships between entities that the subject was required to verify. These sets were:

1. *One-relationship questions*—six questions that required the subject to verify one relationship among the entities in the scenario (see examples in Figure 1, left panel).

2. *Two-relationship questions*—six questions that required verification of two relationships (Figure 1, center panel).

3. *Three-relationship questions*—two questions requiring verification of all three relationships in the scenario (Figure 1, right panel).

In seven of the 14 schematic questions, each relationship in the question accurately reflected those in the scenario. Thus, the correct response to these questions was *true*. In the other seven questions, the relationship(s) were opposite to those in the scenario, thus requiring a *false* response. Note that in order to completely counterbalance the question format across the true–false and balance–imbalance factors (see *Design* section), the following constraint was required. For any given schematic question, either *every* symbol accurately reflected the relationship in the scenario, or *none* did, that is, all were the opposite of those in the scenario.

Of the six one-relationship questions described in Set 1 above, two questions (one true and one false) pertained to the relationship between the people in the scenario (as illustrated at the top of the left panel of Figure 1), and four questions (two true and two false) pertained to the relationship between the people and the impersonal entity in the scenario (middle and bottom of left panel in Figure 1).

Question Set 2 was composed of two questions (one true and one false) about each of the possible subsets of two relationships among the three entities. The three possible subsets of relationships are shown in the center panel of Figure 1.

In Question Set 3, all three relationships were specified in each question.

Four presentation orders (two for each set of scenarios) were prepared, each order consisting of two consecutive random permutations of 28. This resulted in a total of 56 trials that were broken into consecutive blocks in each of which the entire set of 28 questions occurred. Approximately equal numbers of subjects were assigned to each presentation order.

Design

The characteristics of the questions as described above, coupled with the fact that the reversal of relationships changed a given scenario from a balanced to an imbalanced state, meant that the correct response to a particular schematic question was either true or false and concerned either a balanced or an imbalanced structure, depending on the version of the scenario. Thus, collapsing across subjects effectively counterbalanced for scenario effects, question order effects, and their interaction. This resulted in a $3 \times 3 \times 2 \times 2 \times 2$ within-subjects design, the factors being (a) the number of relationships in the schematic question; (b) the particular subset of relationships that the question dealt with; (c) the correct response (true or false); (d) the type of structure (balanced or imbalanced); and (e) the replication block (1 or 2).

Apparatus

Presentation of questions and recording of responses and RTs were controlled by a PDP 11 computer equipped with three ADDS 980 video terminals. Six subjects were run at a time, each proceeding through the trials at his or her own pace.

Each subject sat in an individual soundproofed cubicle with a 12-inch (30.48 cm) monitor and two movable response-button boxes. Subjects were instructed to move the button box labeled TRUE to their dominant hand, to position the boxes comfortably, and to rest their forefingers on the buttons. The schematic questions were centered on the screen of the monitor, which was approximately at eye level.

Procedure

Subjects were seated in their cubicles and were handed an introductory sheet that described the experiment as one concerning "the manner in which individuals learn and use information about the world around them." The sheet also asked the subjects to study "very short descriptions of situations that one might encounter in the course of daily life" and informed them that they would be asked questions about specific details of the descriptions.

After the introductory sheet, the subjects were given two minutes to study each of the scenarios that were typewritten on separate sheets.[2] Following the study period, subjects were given an instruction booklet that described the format of the questions and stressed the importance of answering them by pressing the true or false button as quickly as possible while maintaining perfect accuracy.

The instruction booklet was followed by 12 practice trials (six schematic questions about each scenario). The format of the practice questions was identical to that of the questions used in the actual trials. During the practice trials, the first incorrect response made by a given subject was flagged by an INCORRECT message at the center of the monitor. The second and succeeding errors by that subject were flagged with the message INCORRECT. COMPLETE ACCURACY IS VERY IMPORTANT. SLOW DOWN IF NECESSARY.

Following the practice trials, subjects were asked if they had any questions. During the 56 actual trials that followed, a 2-sec pause was interpolated between a response and the presentation of the next schematic question.

Results

The overall error rate was 4.6% with slightly fewer errors occurring on balanced information (4.2%) than on imbalanced information (5.0%). The analysis of RT includes correct responses only. Data from the practice trials were excluded from the analyses, as were data from trials with aberrant RTs, defined as those more than three standard deviations from the subject's mean (1.3% of the trials).

The principal data are the parameters that describe RT as a function of the number of structural relationships to be verified. Straight lines were fitted to each subject's data, and the parameters (slopes and intercepts) of these RT functions were analyzed in $2 \times 2 \times 2$ within-subjects analyses of variance (ANOVAs), with factors of structure type (balanced/imbalanced), replication block (first/second), and correct answer (true/false). The results reported below are based on data collapsed over replication blocks because there was no effect of replication block on the slopes of the RT functions, $F(1, 31) < 1.0$, and the effect of replication block on the intercepts of the RT functions indicated that subjects merely improved their performance with practice, $F(1, 31) = 8.74$, $p < .006$).

The mean RTs for correct responses appear in Figure 2, together with the means of the parameters of straight lines fitted to each subject's data using a least-squares criterion. In general, the results confirm the predictions regarding the slopes of RT as a function of the number of relationships to be verified. For trials in which the correct response was *true*, the 95% confidence interval for the balanced slope ranges from −95 to −15 msec, whereas the same confidence interval for the imbalanced slope ranges from 84 to 164 msec. For the false trials, the 95% confidence intervals for the balanced and imbalanced slopes were −19 to 61 msec and −32 to 48 msec, respectively.

---

[2] Earlier studies in this program (Sentis, Note 2) indicated that study time is an important factor in this paradigm. When subjects were allowed to allocate their study time differentially between balanced and imbalanced stories, their subsequent recognition performance (in terms of both errors and RT) was markedly superior for imbalanced information. Other studies that employed a single study period for balanced and imbalanced structures also reported superior memory performance on imbalanced information (Gerard & Fleischer, 1967; Spiro & Sherif, 1975). This result appears to be due to the greater distinctiveness of the imbalanced scenarios relative to the balanced ones. The greater salience of imbalanced information apparently commands a disproportionate share of subjects' attention during the study phase and subsequently results in better performance on imbalanced structures during the test phase.

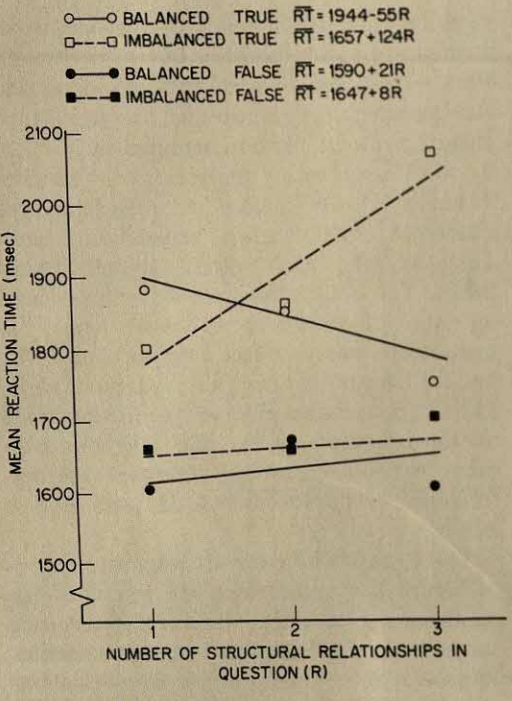

Figure 2. Mean reaction time (RT) for correct responses as a function of number of structural relationships to be verified in the questions. (Least-squares linear functions were applied to individual subject means. Shown are the means of the parameters of the RT functions by type of structure and response.)

Discussion

The results show that the balance schema had a large effect on the processing associated with correct *true* responses, as indicated by the slopes of the *true* RT functions, which differed considerably according to whether the question to be answered concerned a balanced or an imbalanced structure. As can readily be seen in Figure 2, the RT results from the *true* responses confirm the prediction that imbalanced information is not well integrated in memory and thus exhibits a *positive* slope for RT as a function of the number of structural relationships retrieved from memory. In contrast, balanced information yielded not merely a flat slope for the *true* RT function but a reliably *negative* slope. Thus, there is the distinct possibility that the balance schema results in the formation of such highly integrated memory structures that the whole structure is more readily accessed than a subpart. Indeed, it seems that the smaller the subpart, the more difficult the access. In short, not only was parallel processing of the structural relationships indicated, but more intriguingly, the balance schema, by virtue of its integrative function, actually appears to inhibit the processing of subparts of the structure.

In contrast to the *true* responses, the slopes of the RT functions from the correct *false* responses did not differ according to the degree of structural balance. In addition, the RTs to *false* questions were considerably faster than the *true* RTs. These qualitative differences between the *true* and *false* RT functions suggest a two-stage memory search model that is similar to the recognition memory model of Atkinson and Juola (1973). For information stored in long-term store (LTS), Atkinson and Juola propose a recognition model assuming that the subject either makes a fast initial response based on the familiarity of the test item or, if the item is neither extremely familiar or extremely unfamiliar, delays responding until a more extensive search of the memorized information is carried out. As shown in Figure 3, for the present data we assume that the familiarity criterion for a fast *no* is set above the bulk of the "false" distribution and the fast *yes* familiarity criterion is set above most of the "true" responses. The area of extended search between these criteria overlaps most of the *true* distribution, and an account of this extended search process will be given below. Note that the lower tail of the *true* distribution falls below the fast *no* criterion, and thus the incorrect *true* responses (i.e., responses that ought to have been true but were not) should be relatively fast. On the other hand, the upper tail of the *false* distribution lies in the search area, and hence subjects' incorrect *false* responses will occur after a search and should be relatively slow. The RT data for errors are consistent with this reasoning, with the 42 incorrect *true* responses averaging 1,617 msec and the 36 incorrect *false* responses averaging 1,785 msec (although this difference is not statistically significant).

Anecdotal evidence also supports the pro-

posed two-stage model. Subjects often reported that they were sure they had made some errors, despite receiving no feedback during the actual question session. This introspection is in line with the model, which posits that even if the initial familiarity of an item produces a decision to respond quickly, the extended memory search continues and quite likely results in the subject's confirming that he has or has not made the correct response.

Let us now consider the processing that occurs during the extended search initiated for *true* responses. In particular, we wish to address the theoretical significance of the negative slope for the balanced *true* RT function. Of course, our study is not the first to discover that the information about a complete structure maybe more accessible than information about any part. For example, Postman, Bruner, and Walk (1951) found that subjects were able to determine what a defective word ought to be before they noticed which letter in the word was defective. Similarly, Horowitz, Day, Light, and White (1968) showed subjects a word with one letter missing and found that they could report the completed word twice as fast as the missing letter; and Johnson (1975) demonstrated that subjects identify words faster than their constituent letters. Using a paradigm similar to the present studies, Hayes-Roth (1977) observed that after extensive learning of three-part propositions, which presumably resulted in integrated ("unitized") memory representations, two-part subsets of the three-part propositions were verified faster than one-part subsets. In light of these findings, it is reasonable to interpret the negative slope of the balanced RT function for *true* responses as indicating the balance schema results in such a highly integrated cognitive representation of schema-consistent information that subjects found it more difficult to process subsets of the balanced structure than to access it in its entirety. The implication is that there is a cost associated with the integrative function of the balance schema, namely, the integrated memory structure must be decomposed in order to access subsets of it. Because the three-relationship questions require no decomposition, they can be answered most quickly of all. On the other hand, two-relationship questions, since they require that one relationship be removed from the structure prior to responding, are answered more slowly. The one-relationship questions require still another decomposition step and are answered the most slowly.

The present results and the other similar findings discussed above suggest the following processing model for information about social structures varying in their degree of balance. It assumes that structural relationships in the scenarios are transferred to LTS and are maintained there in a particular format (detailed below). The question-answering task requires retrieval of structural relationships into short-term store or working memory, where the decision-making operations needed

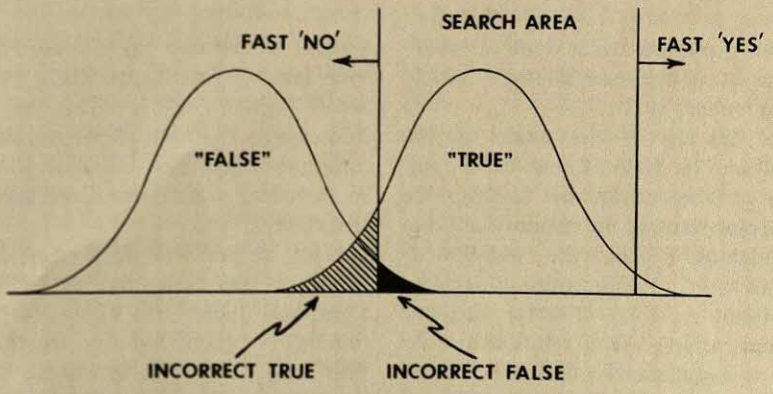

Figure 3. Theoretical distribution of familiarity values for *true* and *false* questions with assumed high and low criteria set to result in the obtained pattern of reaction times.

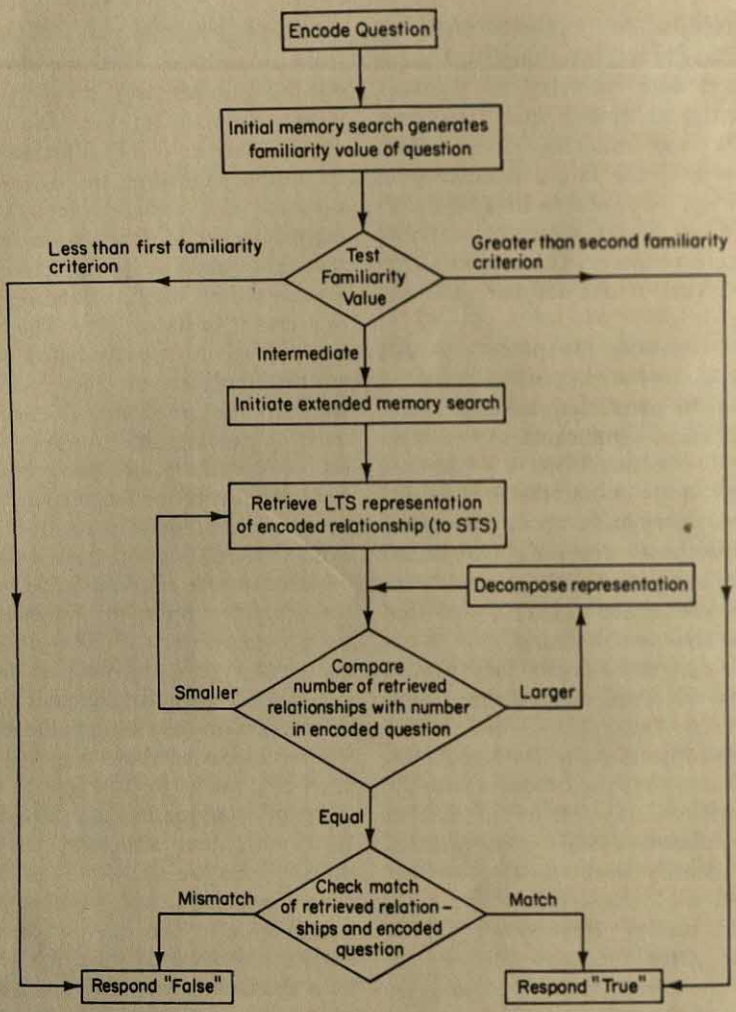

Figure 4. Processing algorithm for answering questions about balanced and imbalanced structures.

to answer the questions occur (for an overview of memory models, see Klatzky, 1975; Shiffrin & Schneider, 1977).

A primary feature of the model is the mode of storage in LTS. Imbalanced relationships are inherently difficult to integrate and are therefore stored in memory as discrete propositions. Thus, the imbalanced P-O-X triads used in the present studies would be stored as three discrete memory representations, one for each relationship. As a result, each imbalanced relationship must be retrieved individually. Balanced information on the other hand, is integrated into unitized nodes that are retrieved in an all-or-none fashion (cf. Hayes-Roth, 1977; Schneider & Shiffrin, 1977). Thus in the present studies, the three balanced relationships that comprise a schema-consistent scenario would be stored as a single unitized memory representation.

With respect to the question-answering phase of this task, the model assumes the algorithm shown in Figure 4. The initial familiarity check results in the relatively "fast and flat" RT functions for the *false* responses that are not affected by the degree of structural balance. Assuming the fast-check

criterion values that are shown in Figure 3, the bulk of the *true* questions generate intermediate familiarity values and would necessitate a more extended memory search.

This extended search incorporates two primary operations—retrieval from LTS and decomposition. The sequencing of these operations depends both on the mode of information storage (discrete propositions vs. unitized nodes) and the complexity of the question to be answered. Consider the sequence of operations that occurs in the algorithm shown in Figure 4 for *true* responses to questions. First, the LTS representation of a relationship in the encoded question is retrieved to short-term store. Next, the number of retrieved relationships is compared to the number in the encoded question. When their numbers are equal, the match of the retrieved relationships with the encoded question is checked and a response is made. Following the first retrieval from LTS, the outcome of the stage that compares the number of relationships retrieved and the number in the question determines the remaining sequence of retrieval or decomposition operations. Imbalanced structures are stored as discrete propositions, and the relationships that comprise them must be retrieved one at a time. Because each relationship to be verified in the question requires additional retrieval operations, the number of such operations covaries with the complexity of the questions pertaining to an imbalanced structure. Thus, the 124-msec slope for the imbalanced *true* RT function represents the time required to search LTS and retrieve a particular structural relationship. In contrast, all of the relationships in a balanced structure are stored in a single unitized node, and consequently a memory search initiated for any single relationship results in retrieval of the entire structure. The storage of balanced structures in unitized nodes permits *true* questions about those scenarios to be answered after only a single retrieval operation, regardless of the number of relationships in the question. However, in order to answer one- and two-relationship *true* questions, the unitized nodes that are retrieved from LTS must be decomposed (cf. Hayes-Roth, 1977). The −55-msec slope for the balanced information reflects the time required for these decomposition operations and comprises the "penalty" in the model.

How reasonable is the model outlined above? First, the RT data from the errors, as well as subjects' introspection regarding these errors, are consistent with the model. Second, the model posits that decomposition operations take place in working memory. These operations consist of transforming the information retrieved from LTS into a format suitable for answering the questions. It seems reasonable to *assume,* therefore, that these relatively simple transformations would be less time-consuming than retrieval from LTS. The relative magnitudes of the slopes of the RT functions representing the decomposition and retrieval operations bear this out, with retrieval taking roughly twice as long as decomposition (124 msec versus 55 msec). Finally, the model predicts equal RTs for *true* responses requiring the same retrieval and decomposition operations. Two conditions in the present experiment required the same set of operations, namely a single retrieval operation with no decomposition operations. The conditions requiring the same set of operations were the one-relationship *true* questions regarding imbalanced structures and the three-relationships *true* questions concerning balanced structures. Given the model, these two conditions should exhibit comparable RTs, and in fact, the predicted values for these conditions (based on the equations in Figure 2) differ by only *2 msec.*

In summary, the present model of the balance schema is a fairly well-specified account of how information concerning social relationships is processed. It accounts for the different signs and magnitudes of the slopes of the RT functions associated with answering questions regarding balanced and imbalanced structures. The model also raises a number of questions. At what point in the encoding sequence is the balance schema activated? How are the retrieval and comparison operations sequenced in working memory? What is the effect of the balance schema on memory for larger social structures? A more complete specification of the model waits on further

research, especially with respect to the temporal organization of retrieval, decomposition, and comparison operations in working memory, as well as the entire encoding process that results in the different modes of storage in LTS.

Our research on the balance schema presents evidence supporting the hypothesis that information consistent with a schema is stored in an integrated fashion. In general, this integrated mode of storage will facilitate retrieval of schema-consistent information and will enhance the processing of such material. This integrative function, however, is a two-edged sword. If the schema results in such a high degree of integration that the relevant information structure becomes unitized, then processing is only facilitated to the extent that there is a match between the amount of information to be retrieved (i.e., the size of the probe) and the size of the unitized structure. Under certain conditions, therefore, the integration function of schemas may be dysfunctional because of the necessity of decomposing the unitized memory representation to access the subparts of the structure.

In certain respects, the integrative function of schemas can be thought of as "chunking," that is, schema-consistent information seems to be processed in larger units than is schema-inconsistent material. Similar results have been obtained in research on the perceptual abilities of chess experts (Chase & Simon, 1973) and masters of the oriental game of Go (Reitman, 1976). This research indicates that experts in these games (individuals with a schema about chess or Go) recognize larger patterns of pieces on the board than do novices (players without a schema). However, differences between the expert and novice do not obtain for randomly placed pieces (i.e., for schema-inconsistent information). Thus, one reason that an expert's play is superior to that of a novice is this ability to process the schema-consistent information in larger units or chunks. In related research, Chiesi, Spilich, and Voss (1979) have shown that the schema, or structured knowledge, possessed by baseball fans allows them to integrate or chunk baseball-related information, thereby enhancing the processing of such information. Moreover, Spilich, Vesonder, Chiesi, and Voss (1979) report that a baseball schema results in the integration of the discrete events in a game into meaningful units or sequences and leads to subsequent recall of larger chunks of game-related information. The findings of Spilich et al. also suggest that a schema's integration or chunking function is hierarchical in nature and results in easier retrieval of higher-order units than of lower-order constituents—a finding completely consistent with our own.

To the extent that the integration function is a general property of social schemas, the present research has a number of implications for social cognition in general and for interpersonal communication in particular. For example, interpersonal communication typically involves the transmission of one chunk at a time, and as a result, efficient communication requires the individuals to use a mutually acceptable chunk size. Consider the case of an expert interacting with a novice. If a novice attempts to query an expert regarding a particular topic, a common source of inefficient communication is the diminutive (low-level) chunks used by the novice to phrase the question. In many cases, the expert does not understand the question and asks the novice for more background information in order to put the question into a meaningful context. The obverse of this problem frequently occurs when an expert does answer a novice's question. The expert's response may often be delivered in large (high-level) chunks incomprehensible to the novice. For example, computer documentation is notoriously difficult to comprehend. It is typically written by a programmer who usually understands not only the particular program to be documented but also the other programs and routines that interface with it, as well as the larger computer system. The crux of the communication difficulty with computer documentation, therefore, seems to be the programmer's failure to decompose the high-level chunks used in an expert's representation of the program into chunks of a size more digestible by novices.

Locus of Control, Interpersonal Trust, and Assertive Behavior Among Newlyweds

This study related two cognitive personality characteristics—locus of control and interpersonal trust—to assertive behavior in a sample of recently married couples. Assertive behavior was measured by the Inventory of Marital Conflicts, an observational procedure in which couples resolve disagreements about hypothetical marital problems. Hypotheses were formulated in terms of individual locus of control as well as two combinations of locus of control and interpersonal trust—internal – low trust and external – high trust. Results showed that internal husbands were more assertive than external husbands in the marital conflict situation, that external – high trust husbands were least assertive, and that internal – low trust wives were highly assertive. These findings are interpreted in light of previous locus-of-control and trust research, as well as in terms of unconventional marital role behavior.

Contemporary research on the marital relationship has focused on the cultural and situational determinants of spouses' attitudes and behavior. Sociologists have emphasized the influence of marital role prescriptions (e.g., Stryker, 1964), whereas psychologists have studied the processes by which spouses shape each other's behavior through reciprocal rewards and punishments (e.g., Weiss & Margolin, 1977).

In contrast to these major interest areas in marital studies, the personality or individual differences dimension of marriage has received relatively little attention in recent years. Historically, this area was once highly popular with researchers. As reviewed by Tharp (1963) and Barry (1970), two research traditions once dominated personality and marriage studies. The first tradition was concerned with the personality correlates of marital "adjustment." From the 1930s through the 1950s, studies consistently found that neurotic traits in individual spouses (especially husbands) were associated with greater marital instability and lower levels of self-reported marital adjustment (Burgess & Cottrell, 1939; Burchinal, Hawkes, & Gardner, 1957; Terman, 1938).

The second personality and marriage research tradition was concerned with whether spouses tend to be similar or complementary in personality characteristics. Although Winch's (1958) research on complementary needs in mate selection stirred considerable controversy, the bulk of the research has supported the similarity hypothesis for married couples (Tharp, 1963). Clore and Byrne (1977) summarized a review of this issue with the following conclusion: "Marriages, and stable marriages in particular, are composed of people with similar personalities, attitudes, and other characteristics" (p. 548).

In recent years, research on the personality aspects of marriage has nearly come to a standstill. At least two problems with past research in this area may help to explain this decline in interest. First, the major findings added little to the common sense notions that "likes marry likes" and that unhappy individuals are apt to have unhappy marriages. Sec-

ond, on a methodological level, these studies suffered from a reliance on global, atheoretical personality traits as independent variables (e.g., neuroticism and maladjustment) and on self-reports of overall marital adjustment as criterion variables. In the past decade, each of these categories of variables has become the object of considerable scholarly criticism. The traditional trait approach has been attacked by personality psychologists like Walter Mischel (1968, 1973) on the grounds that global trait ascriptions ignore the situational constraints on behavior. In addition, marriage researchers have criticized marital adjustment research on both conceptual and methodological bases, arguing that the construct is ill defined and value laden and that marital adjustment inventories have been psychometrically weak (Laws, 1971; Ryder, 1967; Spanier, 1972; Spanier and Cole, 1976). Perhaps for these reasons, related to the turmoil in both personality psychology and marital studies, scholars have turned to other areas of interest.

The present study attempts to break new ground in personality and marriage research through two innovations: first, the use of cognitive personality constructs as opposed to traditional trait dimensions, and second, a focus on an interaction dimension of marriage —assertive behavior. As far as can be determined, no previous study has found a personality correlate of observed marital interaction.

Specifically, this study examines the relationship between the locus of control orientations of individual spouses and their assertive behavior in a marital disagreement situation. Spouses' interpersonal trust expectancies are used as a moderator personality dimension between locus of control and marital assertiveness.

There is no general agreement on the meaning of assertiveness. After examining the various usages found in the psychological literature, Rich and Schroeder (1976) defined assertive behavior in the general sense as "skills that (a) are concerned with seeking, maintaining, and enhancing reinforcement and (b) occur in interpersonal situations involving the risk of reinforcement loss or the possibility of punishment" (p. 1083). In a review of the related marriage research, Olson and Cromwell (1975) have urged that researchers adopt a standard definition of assertive behavior in marriage, namely, "attempts to change the behavior of the (spouse)" (p. 6). Combining elements of these two definitions, the present study conceptualizes assertive behaviors in marriage as attempts to modify the partner's behavior in order to maintain or enhance one's interests during a marital conflict. This definition is deliberately broad and does not distinguish assertive behavior from aggressive behavior. The assertiveness construct is operationalized in this study primarily through the coding of spouses' influence-attempt behavior during a contrived marital disagreement situation.

As defined and operationalized by Rotter (1966), locus of control is a generalized expectancy that one's outcomes are contingent more on one's own efforts or stable personality characteristics (internal) or more on outside forces such as luck, fate, or powerful others (external). Interpersonal trust as defined by Rotter (1967) is a generalized expectancy that other persons can be relied upon to live up to their verbal promises.

Although locus of control has been studied only rarely in the context of ongoing relationships, a considerable body of research using college student groups has found that internals tend to be less malleable to social influence than externals, as well as more persuasive and assertive (see reviews by Phares, 1976, and Strickland, 1977). These findings are consistent with the proposition that internals, believing more strongly that they can control their outcomes, are more likely to develop and use the social skills necessary to manipulate their environment. Extending this line of reasoning to the marital relationship, one can speculate that married individuals' locus of control orientations may be associated with assertive and yielding behavior vis-à-vis their marriage partner. Presumably, internality would be positively associated with assertiveness. According to Rotter's theory (Rotter, 1975), however, generalized locus-of-control expectancies would be only moderately predictive of behavior in a specific,

ongoing behavioral context such as marriage. Rotter believes that the more familiar the situation, the less powerful the influence of generalized expectancies.

To enhance the predictive value of locus of control in the study of assertive behavior in marriage, interpersonal trust was used as a moderating personality characteristic. In other words, this study assumed that the relationship between locus of control and assertive behavior would be mediated by the individual's interpersonal trust expectancies. This strategy was adopted for the following reasons:

1. Interpersonal trust itself has implications for understanding the marital relationship. Evidence presented by Rotter (Note 1) suggests that low trust individuals are more suspicious and behave more competitively than do high trust individuals. High trust persons, in contrast, are characterized in some studies as pleasant and conventional.

2. Previous research has found combinations of locus of control and interpersonal trust to be better predictors of certain criterion behaviors than is locus of control alone. In particular, Hochreich (1974, 1975) has distinguished theoretically and empirically between two types of external males based on their trust scores. External – low trust persons ("defensive externals") have been found to behave much like internals in achievement situations; however, they tend to project blame for failure onto the environment. External – high trust individuals ("congruent externals"), on the other hand, were found to behave in a relatively passive, noncompetitive fashion consistent with theoretical assumptions about externality. This distinction has been found only in males.

3. Finally, in research reviewed by Seeman (1976), sociologists and political scientists have distinguished fruitfully between variations of trust and control expectations. One prominent hypothesis from this research tradition holds that internal control expectancies in the political area, when combined with low trust in government institutions, are associated with greater political activism.

In sum, two combinations of locus of control and interpersonal trust seem to have special importance for assertive behavior in marriage. If internals are generally more assertive than externals, then the low trusting or suspicious internal should be especially likely to protect his or her self-interest in an interpersonal conflict. Conversely, the least assertive behavior should characterize the generally unassertive external who also has a high degree of confidence in the honest intentions of other persons.

Based on the foregoing review, this study hypothesizes that individual spouses' locus-of-control orientations, with interpersonal trust as a moderating personality dimension, will be associated with levels of assertive behavior by that spouse in marital conflict situations. Specifically, it is hypothesized: (a) that internality will be associated with greater assertiveness, (b) that the combination of internality and low trust will be associated with the highest levels of assertive behavior, and (c) that the combination of externality and high trust will be associated (at least in husbands) with the lowest levels of assertive behavior.

Method

Subjects

Eighty-six recently married couples were recruited by mail from marriage license records of first marriages. All had been married less than one year (average 6.4 months), and they may be characterized as a white, college-educated, middle-class group. None had children. The sample was part of a larger pool of recently married couples generated by the Couples Research Project at the University of Connecticut.

Procedure

Couples recruited in the first phase of data gathering went through a two-session procedure in a university setting. During the initial session, couples wrote essays about their relationship, then completed an omnibus questionnaire that included two instruments used in this study. Couples were then invited back for a second session of testing. Although virtually every couple agreed to return, in practice only about half did so. During the second session, couples were administered the locus-of-control and interpersonal trust scales as well as the marital interaction measure. The n for this first group of couples was 28.

Couples recruited in the second phase were administered all the instruments (except the essays) consecutively in one session. The n for Phase 2 was 58. A comparison between the Phase 1 and Phase 2 groups revealed no differences in locus of control, interpersonal trust, or demographic variables (except that Phase 2 wives were more likely to have completed college). The two groups were combined for data analysis.

Instrumentation

1. *Rotter's Internal–External Locus of Control (I–E) Scale* was used to measure locus of control expectancies. A subset of items from Rotter's scale similar to Mirels' (1970) Personal Control Factor was derived through factor analysis, but it yielded no improvement in terms of relating to the marital variables. Hence, only the whole scale score was retained. The I–E scale contains 29 items in a forced-choice format, including 6 filler items. A higher score indicates a more external orientation.

2. *Rotter's Interpersonal Trust Scale* (Rotter, 1967) was used to measure interpersonal trust expectancies. The scale consists of 25 Likert-type items plus fillers. A higher score indicates a more trusting orientation.

3. *The Inventory of Marital Conflicts* (IMC), a laboratory interaction procedure, was used to provide both a process measure and outcome measure of assertive behavior (Olson & Ryder, 1970). The IMC poses a nonthreatening disagreement situation in which spouses typically try to influence each other's behavior. The procedure presents couples with 18 vignettes in which married couples are involved in typical marital disagreement situations (over money, sex, household chores, etc.). Each spouse individually reads the vignettes and answers two main questions about each conflict situation: (a) Who is primarily responsible for the problem? and (b) should a proposal for resolving the conflict be accepted or rejected? (After the partners completed the individual part of the IMC procedure, they filled out the I–E and interpersonal trust questionnaires, which took about 20 minutes.) Finally, the partners are brought together and asked to discuss each conflict situation and reach a consensus on two questions: (a) Who is primarily responsible for the problem? and (b) which of two mutually exclusive solutions is best? This discussion is audiotape-recorded with no experimenter present in the room.

Disagreement is built into the IMC procedure rather than being left to chance. For 12 of the 18 vignettes, the partners are given somewhat different versions of the conflict situation. The husband's version slants the responsibility for the problem toward the wife, whereas the wife's version makes the husband look more responsible for the marital conflict. The couples were told in the IMC instructions that in some cases, they would be reading different perspectives on the same problem.

The IMC yields two types of data: (a) win scores (who won more of the disagreements) and (b) interaction data taken from the taped discussions. The coding of the couple interaction was based on the Marital and Family Interaction Coding System (Olson & Ryder, Note 2), which contains 15 content codes for verbal behavior (plus an uncoded statement category). The codes are divided conceptually into three categories: task related, assertive, and affective. Each statement made during the IMC discussion procedure was coded directly from the audiotape by two independent coders, whose frequency ratings for each code were averaged. Since the concern of this study is with assertive or influence behavior in a disagreement situation, coding was done only for discussions of vignettes on which the spouses had initially disagreed on their individual forms. Because of damage to several tapes, the final n for the IMC interaction data was 80.

Reliability of the IMC variables. Two types of reliability estimates were performed on the IMC data. First, interrater reliability was assessed for each code by examining the agreement between raters on the scores of each code for each spouse. A code's score was its frequency divided by the total frequency for all interaction codes for that spouse. (This procedure controls for amount of talking.) Corrected by the Spearman–Brown formula for two independent raters, the interrater reliability coefficients ranged from .49 to .99, averaging .86 across all the codes for both spouses.

The second set of reliability procedures examined the internal consistency of the IMC data. To compute internal consistency reliability estimates for the IMC variables, the items (vignettes) were divided into two halves that were equal in the degree of disagreement elicited in the sample. As expected from previous studies (Olson & Ryder, 1970), the win scores proved highly unreliable (split-half $r = .12$, with Spearman–Brown correction) and were retained for exploratory purposes only. For the interaction codes, split-half reliability coefficients, corrected by the Spearman–Brown formula, ranged from .31 to .92, averaging .59 across all codes for both spouses. Codes with interrater or internal consistency reliability coefficients of under .60 (averaged over both spouses) were dropped from subsequent analyses. Remaining were 9 of 15 originally coded variables: initiation of discussion (who begins discussion of each vignette), laughter, outcome question (e.g., "What do you think?"), read/content (e.g., "My story says the husband had tried to stop smoking"), self-disclosure (the first spouse to reveal an opinion on the vignette), partisan opinion (statements defending one's opinion), outcome disagreement (the first statement of disagreement during the discussion of a vignette), process disagreement (all subsequent disagreement statements), and disapproval of spouse (criticizing the other's viewpoints or character). Average interrater and split-half rs for those 9 codes were .91 and .72, respectively.

Deriving an assertiveness interaction dimension. Four of the reliable IMC interaction codes are con-

Table 1
Unrotated Principal Components Factor Matrix For IMC Codes

Code	Factor 1	Factor 2	Factor 3
	Husbands		
Initiation	.723	.178	.304
Self-disclosure	.770	.195	−.378
Read	.587	.106	.586
Outcome question	−.052	−.471	.485
Partisan opinion	−.600	.010	−.310
Process disagreement	−.545	.559	.178
Outcome disagreement	−.748	−.067	.433
Disapproval of spouse	−.069	.770	.188
	Wives		
Initiation	.839	.142	.068
Self-disclosure	.637	.532	−.416
Read	.772	−.262	.123
Outcome question	.295	.132	.546
Partisan opinion	−.493	.234	−.607
Process disagreement	−.409	.724	.089
Outcome disagreement	−.625	−.335	.356
Disapproval of spouse	−.150	.626	.589

Note. IMC = Inventory of Marital Conflicts.

ceptually related to assertive behavior as defined earlier—partisan opinion, outcome disagreement, process disagreement, and disapproval of spouse. Each of these codes represents an effort either to stand one's ground or to change the other's opinion—and thus to gain an advantage in the disagreement. The other codes, except for laughter, appear primarily to represent behaviors that facilitate discussion of the vignettes, for example, initiating the discussion of a vignette, asking for clarification, and describing the content of the story.

As an empirical aid to the selection of the assertiveness dimension, a principal components factor analysis was performed on the reliable IMC codes, with laughter excluded. Separate analyses were conducted for husbands and wives. Unities were used as diagonal elements and no rotation was performed. Inspection of the factor loadings in Table 1 reveals three assertiveness-related codes—partisan opinion, process disagreement, and outcome disagreement—loading in the same direction on Factor 1. Three task-related codes loaded in the opposite direction from the assertiveness codes on this factor. This pattern suggests a negative relationship between task-oriented and assertiveness behaviors. The fourth code that had been related conceptually to assertiveness—disapproval of spouse—did not load on Factor 1. However, a decision was made to retain this code as part of an assertiveness dimension for two reasons: first, it represents a theoretically interesting aspect of marital assertiveness, and second, it correlated with process disagreement .41 for wives and .25 for husbands, which suggests that disapproval of spouse has a fair degree of commonality with one other assertiveness code.

For each spouse an assertiveness score was derived by summing the z scores for partisan opinion, process disagreement, outcome disagreement, and disapproval of spouse. Husband and wife assertiveness scores correlated .45 with each other, a finding that suggests a moderate degree of reciprocity between spouses on these assertive behaviors.

Data Analysis

The primary statistical procedure was two-way analysis of variance of locus of control (internal-external) and interpersonal trust (low-high) on marital assertiveness. Separate analyses were performed on the IMC observed interaction dimension and the win score variable. Of central interest were the main effects for locus-of-control and planned t test comparisons focusing on the external – high trust group and the internal – low trust group.

Extreme groups were created on locus of control and trust by dropping out the middle third of each distribution. Mean scores for the remaining husbands were as follows: Internal = 6.6; external = 15.4; low trust = 60.6, high trust = 76.7. The corresponding means for wives were: Internal = 8.0, external = 16.4; low trust = 59.9, high trust = 79.2. Four cells were created for husbands and wives separately in a 2 × 2 design—internal – low trust, internal – high trust, external – low trust, external – high trust.

Exploratory analyses of variances were also conducted on assertiveness difference sources (husband minus wife), and an examination was made of the relationship between couple locus-of-control patterns (husband I–E × wife I–E) and marital assertiveness.

Results

Descriptive Data

A significant difference between husbands' and wives' locus-of-control scores was found, with husbands more internal (M = 11.0) than wives (M = 12.3). (Studies typically report no sex differences on the Rotter I–E scale in college student samples—see Strickland, 1977; Doherty, in press, also found no sex differences in a national probability sample.)

Spouses' locus-of-control scores correlated at .18, which was nonsignificant. Husbands and wives did not differ in average interpersonal trust scores ($M = 68.5$ for both spouses); the correlation between husband and wife trust scores was $r = .07$, which was not significant.

The relationship between locus of control and trust was different for husbands and wives, with husbands' scores on these two variables correlating at $-.18$ and wives' scores correlating at $-.38$, $p < .001$, indicating a positive association between internality and trust. This pattern contrasts with Hamsher, Geller, & Rotter's (1968) report that I–E and trust typically correlate higher for males than for females in college samples.

Two other husband–wife comparisons are worth noting. First, there were no significant husband–wife differences on the individual variables that comprised the marital assertiveness dimension—process opinion, outcome disagreement, process disagreement, and disapproval of spouse. Second, the win score variable also showed no husband–wife mean differences, with husbands winning an average of only 1.1% more of the disagreements in the IMC procedure.

Locus of Control, Interpersonal Trust, and Marital Assertiveness

Table 2 shows the cell means and sizes for the two-way analyses of variance (Locus of Control × Interpersonal Trust) on the IMC marital assertiveness variables. Results for the observed assertive behavior variable will be presented first, followed by results for the win scores and the supplementary analyses. It should be noted that some of the cells in Table 2 have small *n*s, especially the internal – low trust wife group.

Observed assertive behavior. For husbands, a significant main effect was found for locus of control, $F(1, 38) = 7.93$, $p < .008$, indicating that internal husbands had higher assertiveness scores in the IMC marital conflict situation than did external husbands. Table 2 shows that the external – high trust husband group had the lowest average assertiveness score. A planned t test comparison between the external – high trust group and the other three groups combined showed a significant difference, $t(38) = 3.09$, $p < .004$. Consistent with the congruent versus defensive external distinction, the external – high trust group was significantly less assertive

Table 2
Means and Standard Deviations of Marital Variables By Locus of Control and Interpersonal Trust Groups

Group	IMC assertiveness			IMC wins[a]		
	n	*M*	*SD*	*n*	*M*	*SD*
Husbands						
Internal–low trust	10	.232	2.196	10	59.9	19.5
Internal–high trust	13	.706	3.110	13	53.6	10.7
External–low trust	11	−.599	1.970	12	57.8	16.4
External–high trust	8	−2.867	2.076	9	30.1	13.8
Wives						
Internal–low trust	6	3.012	3.221	6	46.5	13.8
Internal–high trust	14	.512	1.140	16	57.6	12.5
External–low trust	14	−.158	2.620	16	51.2	17.1
External–high trust	9	.611	2.735	10	45.4	19.9

Note. IMC = Inventory of Marital Conflicts.
[a] Win points for husband relative to wife. Higher score represents more husband wins, lower score represents more wife wins.

than the external – low trust group, which was indistinguishable from the internal groups.

For wives, the analysis of variance yielded a nonsignificant effect for locus of control, $F(1, 39) = 2.90$, $p < .097$. However, the interaction effect was significant, $F(1, 39) = 4.37$, $p < .043$. Inspection of the cell means suggests that the extremely high assertiveness scores of the internal – low trust wife group were primarily responsible for the significant interaction effect. A planned t test comparison between the internal – low trust wife group and the other groups combined indicated that the difference was significant, $t(39) = 2.53$, $p < .016$. There were no assertiveness differences among the other three groups.

Win scores. Although win scores were found unreliable across vignettes in the IMC, they were retained for exploratory purposes. For husbands, the analysis of variance results showed a pattern similar to observed interaction findings. The main effect for locus of control was significant, $F(1, 40) = 7.60$, $p < .009$, with internals winning more disagreements than externals. However, in this analysis, the very low win scores of the external – high trust husband group created a significant interaction effect, $F(1, 40) = 5.34$, $p < .026$. The other three husband groups averaged more IMC wins than their wives, whereas the external – high trust group won an average of only 30% of their disagreements. The difference was highly significant, $t(40) = 4.76$, $p < .001$. There were no significant effects for wives on the win score variable.

Supplementary analyses. Results of analyses of variance employing mixed husband–wife locus of control groups (Husband I–E × Wife I–E) yielded no significant effects for either observed assertiveness or win scores. The other supplementary analysis examined the relationship between individual spouse locus of control and trust scores and the couple's relative assertiveness (husband minus wife). For husbands, the results showed a significant main effect for locus of control, $F(1, 38) = 5.09$, $p < .030$, indicating that internal husbands when compared to external husbands were more assertive relative to their wives. Of the four Husband I–E × Trust groups, only the internal – low trusters had average assertiveness scores higher than their wives. This difference between the internal – low trust group and the other husband groups combined was significant, $t(38) = 2.04$, $p < .049$. There were no significant effects for wives.

Discussion

The main findings of this study may be summarized as follows: (a) For husbands, internals behaved more assertively in the marital conflict than externals did; external – high trusters were least assertive; (b) for wives, internal – low trusters behaved most assertively in the marital conflict. Husband–wife locus-of-control combinations were not associated with differential levels of assertive behavior.

These findings may be interpreted in terms of previous theory and research on locus of control and interpersonal trust and in terms of unconventional role behavior. To begin with, the tendency for internal husbands to behave more assertively than external husbands is consistent with locus-of-control theory. Since they believe they can control events, internals are thought to pursue valued outcomes more vigorously and persistently than externals do, although relatively little research has examined this hypothesis in social interaction situations. Presumably, supporting one's interests in a marital conflict constitutes a generally valued goal that internal husbands seek more assertively than do external husbands. No explanation is readily apparent for the failure to find a main locus-of-control effect for wives, but one may speculate that succeeding in a more-or-less public marital conflict may be more important to husbands than wives.

The tendency for external – high trust husbands to engage in unassertive marital interactions is likewise consistent with previous research on congruent externality (Hochreich, 1974, 1975). According to this research, reviewed earlier, external – high trust males tend to behave in a passive, noncompetitive manner consistent with theoretical assumptions about externality. Believing that an

interpersonally trustworthy environment controls their lives, these men may have little motivation to win or "make points" in marital disagreements.

Although there is previous empirical research on external – high trust males, the internal – low trust combination has not been highlighted in the literature. However, it seems intuitively reasonable that more vigorous assertive behavior should follow from the belief that one's environment is controllable but socially untrustworthy. In the marital context, the present data suggest that the combination of internality and low trust is associated with greater assertive behavior by wives in marital conflict situations. A supplementary analysis found internal – low trust husbands to be more assertive relative to their wives than were the other husband groups.

The second set of interpretations of these findings takes the position that external – high trust husbands and internal – low trust wives represent personality patterns opposite to the conventional stereotypes of husband and wife role behavior. The external – high trust husband does not match the cultural norm of the active male mastering his environment and representing with appropriate caution the family's interests in the world. Being at the opposite end of the conventional masculinity continuum from the "macho" male, the external – high trust husband is fairly unassertive and yielding in arguments with his wife.

Nonnormative in the opposite direction are internal – low trust wives. Instead of assuming a relatively passive and trusting stance toward the world, these women combine qualities of a strong belief in personal control of their lives and a sense of skepticism about other people's intentions. Women with this orientation are apt to relate to their husbands in an assertive manner, arguing vigorously and persistently for their viewpoints.

In sum, a picture emerges of the internal – low trust wife that is exactly opposite that of the external – high trust husband. Whereas he tends to be passive and uninvolved in marital disagreements, she tends to be active and heavily involved. Unfortunately, because of small cell sizes in the present study, couples with an external – high trust husband and an internal – low trust wife could not be compared with other husband–wife matches.

Conclusion

Findings have been reported here for a sample of recently married couples without children. Whether the same results would hold for couples married longer is problematical. In addition to sampling issues, a further note of caution pertains to the small amount of variance accounted for in most of the statistical analyses. Accounting for such low levels of variance, however, is not surprising in light of the notorious difficulty involved in predicting observed behavior from paper-and-pencil personality instruments.

Within these limits, this study suggests that there may still be life in personality and marriage research. For the first time, cognitive personality variables have been related to observed marital interaction behavior. In addition to breaking new ground in personality and marriage research, the present study has identified two interesting types of married persons, external – high trust husbands and internal – low trust wives. Following a strategy suggested by Rotter (1975), it may be useful in the future to employ a measure of locus of control that is specific to marital outcomes. In this way more powerful predictions may be possible concerning some interesting marital behavior patterns and attitudes, and some new understandings may be reached about the role of individual differences in marriage.

An Examination of Self-Perception Mediation of the Foot-in-the-Door Effect

William DeJong
Brandeis University

In 1966, Freedman and Fraser demonstrated that an individual is more likely to comply with a large request for help if that person has previously agreed to an initial small request—a phenomenon they called the "foot-in-the-door" effect. In the present survey, studies that have sought to replicate the foot-in-the-door effect are reviewed. The adequacy of a self-perception explanation for the foot-in-the-door effect is assessed by examining (a) the importance of the size of the initial request; (b) the effect of noncompliance with the initial request; (c) the impact of salient external justifications for the initial act of compliance; (d) the impact of social labels on subsequent levels of compliance; and (e) attempts at actually measuring changes in self-perception. Alternative explanations of the foot-in-the-door effect are considered and rejected, and directions for future research are outlined.

In 1966 Freedman and Fraser tested the notion that once an individual has complied with a small, sometimes trivial request, that person will be more likely to comply with a larger and more substantial demand made in the future—an effect they christened the "foot-in-the-door" phenomenon. During the last 12 years, social psychologists have continued to be fascinated by those results. How is it that the simple act of assenting to a small request for help can dramatically increase, even double, the probability of a person's agreeing to give help in the future?

Because the foot-in-the-door paradigm has become an important vehicle by which to study the link between self-concept and behavior, it is important to take a step back and ask some basic questions about the progress of this research: (a) Is the foot-in-the-door effect a reliable one? Under how wide a range of situations has it been demonstrated? (b) Self-perception theory (Bem, 1972) is most often used to explain the effect. What hypotheses can be derived from this explanation, and what evidence has been gathered for each of them? (c) How else can the phenomenon be explained? What is the evidence for and against the alternative propositions that have been offered? (d) What directions can future research take? It was in the hope of answering these questions that the present article was designed. First, I begin with a review of the Freedman and Fraser (1966) experiment.

The Freedman and Fraser Study

The procedure of their experiment was straightforward. A male experimenter first contacted several suburban housewives in their homes, identifying himself as a member of either the Community Committee for Traffic Safety or the Keep California Beautiful Committee. The initial requests he made of these women were small and innocuous, and almost all of the subjects agreed to them. Half were asked to display a small sign in the front window of their homes. The other sub-

Preparation of this article was supported in part by Public Health Service Postdoctoral Fellowship 1/F32/MH07294-01.

My deepest appreciation is extended to Teresa Amabile, Nancy Cantor, David Funder, Albert Hastorf, Mark Lepper, and David Rosenhan for their comments on an earlier draft of this article.

jects were asked to sign a petition advocating certain legislation. These requests were concerned with one of two issues, driving safety or making California more beautiful.

Two weeks later, the housewives were again contacted. A different experimenter, who claimed to be a representative from the Citizens for Safe Driving, asked the women if they would be willing to have a large, ugly billboard reading "Drive Carefully" installed in their front yard for a period of one week. Thus emerged a simple two-way factorial design. For half of the subjects this second request was like the first in terms of the action required of them (i.e., displaying a sign). For those who had previously signed a petition, the action now required of them was quite different. As a cross-dimension, the issue of concern was the same as before for half of the subjects (i.e., driving safety). Those originally approached by the Keep California Beautiful Committee were now dealing with a different issue.

Freedman and Fraser demonstrated a foot-in-the-door effect of remarkable strength and generality. Each of the four experimental conditions produced significantly greater compliance with the final request than did a control condition in which subjects were not approached with a first request: Only 20% of the subjects in that control condition were willing to have the billboard installed, compared with 55% of the experimental subjects. To be sure, those subjects for whom the second request was similar to the first along the two dimensions of issue of concern and mode of action were somewhat more helpful than subjects in the other three experimental conditions, but that difference did not approach statistical significance. This increased compliance effect did not seem to depend much on the type of request that had been made initially. Even the seemingly trivial action of agreeing to sign a petition about the need to "keep California beautiful" more than doubled the probability that a subject would agree to display a billboard that exhorted motorists to drive more safely. The exciting feature of these results is that the effect cannot be explained merely in terms of either the subject's involvement with a particular experimenter or her increased commitment to a certain issue or mode of action. As Freedman and Fraser recognized, a more complicated (and psychologically interesting) explanation is required.

Attempts at Replication

Since Freedman and Fraser's (1966) original report, several replications of the foot-in-the-door effect have been attempted. Before this research is reviewed, the criteria that any study must meet before it can be considered a valid replication attempt should be listed:

1. Obviously, a proper control group, consisting of subjects not receiving an initial request, must be included as part of the experimental design. Three studies must be excluded for this reason: Harris, Liguori, and Joniak (1973); Harris and Samerotte (1975); and Schmidt (1973). The first two, in all fairness, were not explicitly designed to test for a foot-in-the-door effect.

2. The data analysis must include all subjects assigned to the experimental condition and not just those who agree to the first request. Any analysis that excludes those not complying with the first request can be criticized on grounds of differential subject self-selection. Studies by Arbuthnot et al. (1976–1977) and Beaman, Svanum, Manlove, and Hampton (1974) must be excluded from consideration because of this problem.

3. High compliance with the initial request must be obtained. Harris, Liguori, and Stack (1973, Study 3), for example, failed to obtain a significant foot-in-the-door effect, but interpretation of their findings is made problematic by the fact that only 42% of their experimental subjects agreed to the first request (see also, Dutton & Lennox, 1974). Ideally, of course, 100% of the subjects would consent to the first request, but that goal is rarely obtained. Some studies have reported a significant foot-in-the-door effect with a rate of initial compliance as low as 67% (e.g., Freedman & Fraser, 1966, Study 1).

It should be noted that in testing for significant foot-in-the-door effects, each experimental group should be compared individually with the control group. Some studies (e.g.,

Cann, Sherman, & Elkes, 1975; Harris, 1972, Study 1) combined experimental groups in their analyses, and the data from such studies have been reanalyzed when possible.

Table 1 summarizes known replications of the foot-in-the-door phenomenon that had been attempted by the time of this review (November 1978). The table lists the two requests made of the subjects, the rate of compliance with the second request for both the experimental groups and the no-initial-request control group, and the conclusions drawn from appropriate statistical comparisons.

A glance at the table shows that a significant foot-in-the-door effect was not always found. It is unwarranted, however, to declare that the effect cannot be reliably obtained. It must be noted that only a few studies (Cann, 1976; Cialdini & Ascani, 1976; Cialdini, Cacioppo, Basset, & Miller, 1978; DeJong & Funder, 1977, Study 1; Harris & Samerotte, 1976; Miller & Suls, 1977; Tipton & Browning, 1972; DeJong, Note 2) showed the percentage of compliance with the second request for one or more experimental groups to be lower than or equal to that for the control group. Thus, almost all of the failures to replicate were in the predicted direction, but did not reach traditional levels of statistical significance. And as noted previously, two failures to replicate (Dutton & Lennox, 1974; Harris, Liguori, & Stack, 1973, Study 3) are difficult to interpret because of the very low levels of compliance with the first request in the experimental group.

The subsequent discussion of many of these studies reveals other potential explanations for failures to replicate. They can be mentioned here briefly. First, the initial request must be large enough to cause people to think about the implications of their own behavior; if the request is too small, the effect will probably not be obtained (Seligman, Bush, & Kirsch, 1976). Thus, for example, it may be that a request to take a small card is too small to increase compliance with a high-cost request like donating blood (Cialdini & Ascani, 1976). Moreover, some evidence suggests that if the initial request is too large, the probability of obtaining the effect will be reduced (Baron, 1973; Miller & Suls, 1977). Second, people must feel that their initial compliance resulted from the exercise of free choice, not because of pressure to comply (Uranowitz, 1975; Zuckerman, Lazzaro, & Waldgeir, in press). Fish and Kaplan's (1974) findings are difficult to interpret for this reason. Subjects in their experiment were first asked to write an essay on various ways of fighting poverty, but they were asked to do this as part of a class about the poverty program. It is possible, then, that the subjects may have felt pressured into writing the essay because they saw it as a class assignment.

A key issue of concern is the generality of the foot-in-the-door phenomenon. Under how wide a range of situations has it been demonstrated? As Table 1 reveals, most of the requests that have been made of subjects involved little time or effort. But some did involve major commitments on the part of the subjects. For example, Lowman (1973) used the foot-in-the-door technique to increase household participation in a complicated trash recycling program. In one study, Freedman and Fraser (1966, Study 1) induced housewives to allow a survey team of five or six men to come into their homes to classify the household products they used.

The length of the delay between the two requests has also been varied. The foot-in-the-door effect has been demonstrated with delays between the two requests of up to two weeks (e.g., Freedman & Fraser, 1966, Study 2; Harris, 1972, Study 2), but most successful replications have involved much smaller delays of a day or two. The effect of delay has never been systematically explored, save Cann et al.'s (1975, Study 1) comparison between delay (7–10 days) and no-delay procedures (see Table 1). The length of the delay itself may be less important than whether the occasion of the second request somehow reminds people of their earlier behavior.

The degree of similarity between the two requests is an important dimension as well. Unfortunately, most investigators have employed requests that share many common features, so that the robustness of the foot-in-the-door phenomenon has rarely been put to

Table 1
Replications of the Foot-in-the-Door Effect

Study	First request	Second request	Results[a]	Conclusion
Baer, Goldman, & Juhnke (1977)	(1) Give the time to experimenter (2) Same as (1); later misinformation given to different experimenter	Correct misinformation given to experimenter by another elevator passenger	(1) 70 (2) 35 (C) 33	FITD No FITD

Note. The first condition in a study is indicated by (1), the second condition by (2), and so on; results are described accordingly; (C) = the no-initial-request control group; FITD = the foot-in-the-door effect.

[a] Results are reported as the percentage of subjects complying with the second request. A chi-square test (corrected for continuity) was executed for comparisons between individual experimental groups and the control group. If $p < .10$, it is concluded that the foot-in-the-door effect was successfully replicated. If a chi-square could not be executed based on the information provided by the authors, the conclusions based on the authors' own statistical comparisons are reported.

[b] Data reported are for subjects run by the male experimenters. Percentage compliance for subjects run by the female experimenters is not reported, but no FITD effect was found. For Condition 2 (male experimenters), $p > .10$ by chi-square, according to Baron (1973).

[c] Data reported are for verbal compliance with the request. Actual compliance was as follows: (1) 10%; (C) 20%.

[d] Data are reported in terms of average summed difficulty level of volunteered activities; data on percentage compliance are not reported. In a previous experimental session, all subjects run in this study were given false physiological feedback, which led them to believe they might harbor racial prejudice.

[e] Data have been collapsed across the variable of type of food to be purchased by the experimenter.

[f] Only those who helped the elderly woman were included as subjects in the experimental condition. Despite the bias toward confirmation this procedure created, no foot-in-the-door effect was found.

a severe test. For example, most studies that ask the subjects to participate in a survey as the initial request also seek their participation in a second survey. As noted previously, Freedman and Fraser (1966, Study 2) actually manipulated the degree of similarity between the two requests in terms of the issue involved and the mode of action required of subjects, but they found those factors to have little impact on compliance with the second request. Seligman, Miller, Goldberg, Gelberd, Clark, and Bush (1976) also failed to find generally higher compliance when the two requests were similar.

Self-Perception Explanation

Freedman and Fraser (1966) were surprised to learn that the size of the foot-in-the-door effect they obtained did not depend on the nature of the first request. As noted before, possible explanations for the effect centering around subjects' commitment to a particular experimenter, organization, issue, or mode of action were effectively ruled out. To account for their unexpected results, they offered the following explanation:

> What may occur is a change in the person's feelings about getting involved or about taking action. Once he has agreed to a request, his attitude may change. He may become, in his own eyes, the kind of person who does this sort of thing, who agrees to requests made by strangers, who takes action on things he believes in, who cooperates with good causes. (Freedman & Fraser, 1966, p. 201)

Thus, the self-perception mediation of the foot-in-the-door phenomenon involves a two-stage process. First, people must observe their own behavior and the situational context in

which it occurs and, from those data, make an inference about their own dispositions and attitudes. It has been argued that subjects comply with the initial request in the apparent absence of any external inducements and then decide on the basis of that evidence that they are the kind of people who cooperate with good causes or help out other people.[1] Second, this changed self-perception is thought to increase the probability of their performance of similar kinds of action in the future. As presently articulated, self-perception theory does not adequately explain the processes that mediate this last step (cf. Bem, 1972).

The self-perception explanation of the foot-in-the-door phenomenon has led to the formulation of several testable hypotheses. The evidence for each of these is now considered.

Size of the Initial Request

A straightforward prediction derived from self-perception theory is that the larger the size of the first request to which people agree, the greater the probability of their compliance to the second larger request. In other words, the greater the costs of compliance with the initial request, the more likely it should be for people to find dispositional meaning in their behavior. To test this hypothesis, Seligman, Bush, and Kirsch (1976) first asked subjects to answer either 5, 20, 30, or 45 short questions for a survey on reactions to the energy crisis and inflation. There were no differences among those four conditions with regard to compliance with the first request for help. Later, subjects were called back by a different experimenter representing the same survey group and were asked to answer 55 more questions. Unexpectedly, subjects in the 5- and 20-question groups were not more likely to answer the 55 questions than were control subjects contacted for the first time. However, the two larger initial requests were effective in inducing significantly higher rates of compliance with the second request.

Seligman, Bush, and Kirsch recognized the possibility that sufficiently large initial requests might discourage subsequent compliance, but evidence for that was not found in their study. It should be noted that subjects in all cases were told the survey would require only "a couple of minutes," thus making even the larger requests seem relatively small. A study by Miller and Suls (1977) suggests the possibility of a curvilinear relationship between size of the initial request and subsequent compliance. Subjects in their experiment were asked to give street directions to a first experimenter, the directions being either difficult or simple to explain. Compared with control group subjects, those who gave the simple directions were more likely to help a second experimenter pick up his dropped groceries a few moments later. Those who gave the difficult directions were less likely to help. Existence of a curvilinear relationship, of course, could not be explained by self-perception theory alone.

Agreement to the Request Versus Actual Performance

It could also be predicted from self-perception theory that compliance with the second request would be more likely if subjects actually performed what was asked of them in the initial request than if they agreed to comply but were never called upon to carry out their promise. The only study that directly addressed this issue is an experiment reported by Freedman and Fraser (1966, Study 1). Housewives in the so-called agree-only condition were asked to participate in a consumer survey about household products; those willing to help were told the survey would be conducted at a later time. Subjects in the performance condition actually participated the survey. In a later call, the same experimenter asked subjects if they would permit

[1] Self-perception theory has not articulated well the exact nature of the self-perception changes that are said to occur. It is not clear, in the case of most foot-in-the-door studies, whether subjects classify their behavior as *compliance* or as *helping*. This uncertainty is due to the fact that most experimenters use compliance with a request for help as their dependent measure (see Table 1). Experiments that instead require subjects to initiate help giving (e.g., Miller & Suls, 1977; Uranowitz, 1975) suggest most subjects may view their assent to the request as helpfulness.

urvey team to come into their homes to list ne household products they used. Whereas 22% of the control group subjects agreed to hat request, over half the subjects in the performance condition did so. In contrast, a mere 33% of the agree-only condition subjects complied with that request. A clear heoretical interpretation of these results is made difficult by the fact that subjects in the agree-only condition did not learn the exact size of the request to which they had agreed. Their compliance to the second request may have been lower only because they guessed the initial request to be quite large (cf. Miller & Suls, 1977). Parenthetically, it must be noted that other experimenters have shown that actual performance of the initial request is not requisite in demonstrating the foot-in-the-door effect (e.g., Snyder & Cunningham, 1975; Zuckerman et al., in press).

Effect of Noncompliance With the Initial Request

Self-perception theory led Snyder and Cunningham (1975) to predict that subjects induced not to comply with an initial request would be less likely to comply with a second request. In their experiment, one group of subjects was first asked to participate in a 50-question telephone survey, a request sufficiently large to guarantee almost universal noncompliance. Two days later, a different-sexed experimenter representing a second organization asked subjects to answer 30 questions. Consistent with their prediction, subjects initially approached with the large request were less compliant with the second request than were subjects in the control group. Similar results were reported by Cann et al. (1975) and Reingen and Kernan (1977). These studies support the idea that induction of initial noncompliance leads people to perceive themselves as the kind of people who do not comply with such requests. One might predict that the smaller the request that people refuse, the lower the probability of their compliance to a second request; this proposition remains to be tested. An added complication arises when the timing of the second request is considered. In two studies, Cann et al. (1975) reported that noncompliance with a large initial request actually led to greater compliance when the second request was made immediately after the first, rather than after a delay period of several days. For example, one study showed that 90% of the subjects agreed to an immediate second request after having refused the experimenter's initial large request, compared with 50% in the control group. Only 29% compliance was obtained when that second request was made 7–10 days later.

These findings replicate an effect first demonstrated by Cialdini et al. (1975), which they dubbed the "door-in-the-face" technique. Quite simply, these authors claimed that if an experimenter first approaches subjects with an unreasonable request that is sure to be refused, but then immediately asks a smaller favor, subjects will view the experimenter's action as a concession. The subjects, in turn, will feel normative pressure to reciprocate that concession, and they will respond to that pressure with compliance with the second request. Replications of this effect abound (Cialdini & Ascani, 1976; Miller, 1974; Miller, Seligman, Clark, & Bush, 1976; Reingen, 1977).

In one experiment, Cialdini et al. (1975) demonstrated that the subjects' perception of the encounter as a kind of bargaining situation probably underlay the effect. In the rejection–moderation condition, both requests for help were made by the same experimenter. In the so-called two-requester condition, subjects' noncompliance with the first request was followed immediately by another request put to them by a second experimenter. This second experimenter was seemingly unrelated to the first, but subjects knew this person had overheard their conversation with the first experimenter. Whereas a control procedure produced a 31% compliance rate, 55% of the rejection–moderation condition subjects consented to the second request. But when that same second request was made by a different experimenter, only 10% of the subjects in the two-requester condition complied, a result consistent with those reported by Snyder and Cunningham (1975). The authors argued that subjects in the latter condition could

not interpret the second request as a concession, simply because it was made by a different experimenter.[2]

Why do subjects in the door-in-the-face procedure who do not comply with the initial large request not come to see themselves as the kind of people who refuse such requests, as Snyder and Cunningham's (1975) results might lead us to expect? Even-Chen, Yinon, and Bizman (1978) argued that the initial requests used by Cialdini et al. (1975) and others were too large for subjects to draw dispositional inferences from their failure to comply. Implicit in their argument is the suggestion that subjects must believe the request is one to which someone (though not they) might consent in order for a self-perception change to occur. In their study, when subjects refused a large, but not reasonable, first request, they were less likely to agree to a second smaller request. Only those who refused an extremely large request showed a subsequent door-in-the-face effect. These results are suggestive, but Even-Chen et al.'s argument cannot account for the results obtained by Cialdini et al. In the earlier experiment, whether a door-in-the-face effect or a result consistent with self-perception theory was found depended solely on who made the second request.

In general, research on the effect of initial noncompliance has been supportive of the self-perception hypothesis. Only under a special set of circumstances, that is, when the first request is extremely large and the second request can be viewed as a concession on the part of the experimenter, does an initial refusal not lead to subsequent refusals.

Effect of Consensus Information

The self-perception analysis of the foot-in-the-door effect leads to the prediction that if subjects were informed they were not unique in their compliance with the initial request, they would be induced to see their behavior as determined by situational pressures and not to view it as having any implications for their own traits or attitudes (cf. Cook, Pallak, & Sogin, 1976; Cooper, Jones, & Tuller, 1972). In one recent experiment designed to test this prediction (DeJong, Note 2), shoppers were approached individually by a physically able male experimenter and shown a card on which was written the resolution of a petition formulated by a group called the Upper Valley Foundation to Help the Handicapped. After reading the resolution, 87% of the subjects agreed to sign the petition. At that point, some subjects were shown a petition with many signatures and one blank space at the bottom (consensus condition). As they signed, the experimenter said, "As you can see, almost everyone we've asked has signed our petition." The other subjects were shown a completely blank petition, and as they signed, the experimenter noted that they were the only ones so far to do so (nonconsensus condition). When the subjects walked on, a second male experimenter dropped a quarter as he walked some 15 to 20 feet ahead of them. Thirty-two percent of the subjects in the no-initial-request control group notified the second experimenter of his loss, whereas 64% of those told that many people had signed the petition did so. Unexpectedly, only 28% of those told they had been unique in their agreement to sign helped the second experimenter.

Consensus information is more psychologically complex than attribution theorists have admitted (cf. McArthur, 1973). In addition to pointing to the power of situational constraints on behavior (Kelley, 1967), consensus information can help define the behavioral norms that are operative in a specific context. Subjects in the consensus condition may have helped the second experimenter more often because they were reminded that helping others was appropriate behavior. In addition,

---

[2] Pendleton and Batson (1979) offered a self-presentation explanation of the door-in-the-face technique, suggesting that subjects are motivated to comply with the second request to avoid being perceived as unhelpful. Although the results for Cialdini et al.'s (1975) two-requester control group seem to counter this alternative, Pendleton and Batson argued that the phrasing of the second experimenter's request ("But maybe you could help *me*") may have induced reactance, thus producing a low rate of compliance in that condition. Further research is needed to resolve this controversy.

consensus information can reaffirm the reasonableness of one's own behavior. Subjects in the nonconsensus condition may have been shocked to learn of their unique status and may literally have been "lost in thought" when the second experimenter dropped his quarter. To date, no foot-in-the-door study involving the introduction of consensus information has yielded results consistent with self-perception theory.

Presence of External Justification

Theoretical analyses of attributional processes (Kelley, 1967) propose that people assign dispositional meaning to behavior after a careful assessment of the possible explanatory power of controlling influences in the environment. Thus, a self-perception account of the foot-in-the-door phenomenon stresses that the amount of external pressure used to induce compliance with the initial request is paramount. If those external pressures provide people with an adequate explanation of their behavior, they will not be led to infer anything about their own traits or attitudes. Under those circumstances, an increased probability of compliance with subsequent requests for help would not be expected. Indeed, Lepper (1973) even suggested the possibility of an "overjustification" effect; that is, if people comply with an initial request under conditions of strong external justification, they may come to infer that they are intrinsically motivated and that they are the kind of people who agree to such requests only when external pressures are present. As a result of this kind of changed self-perception, people may actually come to be less likely to comply with future requests when those kinds of pressures are absent.

The impact of external justifications for the initial act of compliance on subsequent helping was demonstrated by Uranowitz (1975). Female shoppers were asked by an experimenter to watch his grocery bags while he ran back to retrieve a lost article. In the high-justification condition, he claimed he had lost a wallet containing a lot of money; in the low-justification condition he said that he had dropped only a dollar bill. The assumption, of course, was that subjects in the high-justification condition would believe that circumstances demanded their compliance and that anyone faced with such a request would agree to it. When the first experimenter returned with the lost article, the subject proceeded on her way. A female experimenter later dropped a package in the subject's path, and the subject's response was noted. The results were striking. Eighty percent of the subjects in the low-justification condition helped the second experimenter, whereas only 45% of the high-justification and 35% of the control subjects did so.

Zuckerman et al. (in press) investigated this same problem using an experimental procedure modeled after that used by Snyder and Cunningham (1975). Housewives were first asked to take part in a 5-minute telephone survey; some were promised a monetary payment in exchange for their cooperation, and others were not. If a subject agreed to participate, she was told that the interview would be conducted at a later time. Subjects promised the monetary payment were told they would receive a check after the interview. Two or three days later, the subjects were called by a second experimenter representing a different service organization and were asked to consent to a 20-minute interview. Forty-five percent of the control group subjects agreed to that request, whereas 64% of the subjects promised no money consented to the interview. In contrast, only 33% of those promised a monetary payment in return for their initial compliance agreed to the second request. Similar results were reported by Reingen and Kernan (1977).

DeJong and Funder (1977), however, found the monetary payment to have the opposite effect. The day after their participation in a 15-question survey, subjects in the payment condition received the $2 that had been promised them in exchange for their help. Subjects were later asked to take part in a 50-question survey being conducted by a second organization. Fifty-six percent of control subjects never before contacted agreed to the second request, whereas 78% of the subjects in the payment condition did so. These findings were unexpected. It was thought that the

actual receipt of money by subjects in the payment condition would increase the salience of the external justification for their compliance with the first request. A follow-up study showed that this finding was not due to subjects' expectation that they would be paid for helping with the second survey. When the second caller informed subjects they could not be paid for their help, the pattern of results was virtually unchanged. One possible explanation for this unexpected set of results is that a letter that accompanied the payment may have labeled subjects as "doers" (cf. Kraut, 1973). That certification may have had greater implications for subjects' self-perceptions than did the small monetary payment.

Finally, in a study conducted by DeJong and Musilli (Note 3), subjects were approached at home with a small initial request made by a female experimenter who appeared to be either handicapped or physically normal. It was hypothesized that subjects approached by the disabled experimenter would feel psychological pressure to comply with her request and would, in turn, attribute their compliance to the fact of her disability. The experimenter asked half the subjects to answer questions for a survey on special parking facilities for disabled drivers for a group called Friends of the Handicapped. The others were told that the experimenter represented Friends of the Environment and that the questions concerned special parking for compact cars. Two days later, subjects were called on the telephone by a second experimenter and were asked to participate in a 30-minute survey on traffic safety for a different organization. The hypothesis was partially supported. Fifty-six percent of the subjects approached by the handicapped experimenter for Friends of the Handicapped complied with the second request, whereas 40% of control subjects did so. However, only 41% of subjects approached by the handicapped experimenter for Friends of the Environment complied with the second request.

In sum, evidence is generally consistent with the proposition that high external justification for initial acts of compliance can dampen the probability of subsequent compliance. Only one study found no such effect at all (DeJong & Funder, 1977), and there is a plausible explanation for that failure. Little evidence for an overjustification effect exists; only Reingen and Kernan (1977) and Zuckerman et al. (in press) reported results for a high-justification condition to be actually below those for a control group, and these differences were small. One possible reason for not finding overjustification effects is that subjects in these studies were not preselected for their high level of initial intrinsic or altruistic motivation.

There may be circumstances under which high external justification for initial compliance actually leads to higher levels of subsequent compliance. Such an outcome might be anticipated if people believe that behavior that is truly intrinsically motivated is more highly regarded than that which is thought to arise in response to external pressure (cf. Nemeth, 1970). Thus, when subjects' self-esteem (or their good name) is threatened by the perception that they have complied in response to the dictates of external contingencies, they may be motivated to be more helpful in the future when such pressures are absent. A report by Upton (1973) is consistent with this notion. He found that previous blood donors classified as intrinsically motivated did not respond well to an appeal for donations that offered money in exchange for a pint of blood. When no such bribe was offered, the percentage of such subjects willing to donate was almost 30 percentage points higher. It is conceivable that subjects offered the bribe wished to avoid the perception that they were motivated to help others only as a means of garnering rewards for themselves.

Effect of Social Labels

Sociological theories of deviance stress that society encourages those whom it labels as deviant to learn and accept a deviant role identity. Once such people come to share this definition of themselves, the changed self-image is believed to sustain their deviant behavior (see Schur, 1971). Although these theories focus almost exclusively on labels of deviance and generally ignore positively val-

enced labels, their basic propositions can still easily be translated into the language of self-perception theory. Though actual behavior (and the context in which it occurs) may provide the clearest evidence about one's traits or attitudes, self-perception theory recognizes that a self-definition or label provided by others may serve as an important source of information about one's dispositions (cf. Miller, Brickman, & Bolen, 1975) or at least may signal to people that their behavior and its implications for their self-image should be reflected on, thereby energizing a self-perception analysis.

This proposition was put to the test by Kraut (1973). First, a male experimenter went to subjects' homes and solicited contributions for the Heart Association. If subjects made a donation, they were randomly assigned to be in a labeled or a nonlabeled condition. Subjects receiving the charitable label were simply told, "You are a generous person. I wish more of the people I met were as charitable as you." Subjects who did not contribute were also assigned to a labeled or a nonlabeled condition. Subjects receiving the label were frankly told that they were "uncharitable." One or two weeks later, a second experimenter contacted the subjects and asked for a donation to a fund-raising drive for multiple sclerosis. (Unfortunately, a control group consisting of subjects receiving only the second solicitation was not run.) As Kraut predicted, 62% of those given the positive label donated the second time, whereas only 47% of the nonlabeled subjects did so. Kraut recognized that this effect could be explained in terms of a social reinforcement model if the charitable label constituted a reward for the subjects. He also found that those who did not donate the first time gave somewhat less when they had been branded as uncharitable by the first experimenter, but this difference was not significant.

The impact of labels on self-perception and subsequent behavior was also examined in a study conducted by Paulhus, Shaffer, and Downing (1977). Prior to their actual donations, blood donors were asked to read communications that were designed to label their motives for giving blood. Half the subjects read a communication that emphasized altruistic motives, and as a cross-dimension, half the subjects were told about the personal benefits they would receive (e.g., free blood in case of emergency). After donating, subjects filled out a questionnaire that included an item on their plans for giving again within the next year. The results showed a main effect for salience of altruistic motives, such that subjects led to feel they had acted altruistically reported a greater likelihood of future donation.

McArthur, Kiesler, and Cook (1969) labeled some subjects as doers (people who know what needs to be done and then take the appropriate action) on the basis of bogus test results. This positive label increased the proportion of subjects willing to help distribute antipollution leaflets only when subjects had been told that their doer personality qualified them to be paid for their participation in a second experiment. Apparently, subjects' belief that being a doer was a saleable quality strengthened the impact of the label, either because it made the feedback more convincing or simply because the subjects thought about it more.

In contrast, Steele (1975) expected labels to have effects different from those predicted by self-perception theory. He argued that a negative label (name-calling) that impugned subjects' character would motivate them to take action that would restore their self-esteem, thus increasing the probability that they would comply with a later request for help. Because positive labels would not do this, Steele expected them to have little impact on help giving. In this study, an experimenter claiming to be a pollster contacted subjects by telephone. In the relevant-negative-name condition, subjects were lambasted for being "apathetic about the welfare of others," whereas subjects in the irrelevant-negative-name condition were criticized for their lack of concern for driving safety. Recipients of the relevant-positive-name message were praised for their desire to help their fellow man. (No irrelevant-positive-name condition was run.) Two days later, subjects were called by a second experimenter representing a food cooperative in a lower income

neighborhood. To help the cooperative achieve its goal of "aiding the less fortunate," subjects were asked to compile a detailed list of the quantities and brands of foods and household items used in their homes. Compared with a control group never before contacted, subjects receiving the positive label were more likely to help, though not significantly so (cf. Kraut, 1973). On the other hand, virtually all subjects in both negative-name conditions promised to help out, and most actually did so. This effect was replicated in a second study.

The name-calling procedure employed by Steele (1975) differs from the labeling procedure used by other researchers in one important way. The labels used by others were based either on recent behavioral evidence (Kraut, 1973) or on the results of phony psychological tests (McArthur et al., 1969). In contrast, no such evidence substantiated the claim made by Steele's experimenter. This suggests that whether the negative label induces a change in self-perception may depend on the degree to which subjects' future behavior can belie the label. If refutation of the label is still possible, it may not lead to a change in self-definition, but may lead to a vigorous effort to defend self-esteem or to assuage guilt.

This possibility was explored in a recent study by Gurwitz and Topol (1978). Students at a large suburban university were first contacted by telephone and accused of not taking advantage of the opportunities afforded by a nearby city. This accusation was directed at subjects as members of a group (students at the university) or as individuals. Before the accusation was made, half the subjects were asked how many times in the past few months they had gone into the city, the modal answer being zero. The other subjects were not led in this way to provide evidence in support of the accusation. Later that evening, a second experimenter had subjects fill out a questionnaire concerning their interest in a number of student-organized activities in the city.

When subjects had not been led to provide evidence in support of the accusation, the degree to which they later belied the label depended on whether the accusation had been made about them as individuals or as members of a group. When they were seen as part of a group, they indicated more interest in the activities, thus belying the label. In contrast, when the subjects had been led to provide such evidence prior to the accusation, they were more likely to disconfirm the label when it had been directed at them as individuals. Similar results were found in a laboratory study conducted by Gurwitz and Topol (1978) in which subjects were labeled as being low in self-confidence. Why subjects' responses to the label depended so greatly on whether it was applied to them individually or as members of a group is not clear.

In sum, although the effect of positive labels has been fairly consistent across several studies, the impact of negative labels on subsequent behavior presents a more complicated picture.

Measurement of Altered Self-Perceptions

Perhaps the most convincing evidence in support of the self-perception explanation of the foot-in-the-door effect would come from studies that actually measured the changes in self-perception that are thought to occur. Unfortunately, this kind of direct evidence is hard to come by. A long catalog of excuses for this failure can be offered, most of them pointing to possible inadequacies in design and measurement (see Bem, 1972; Lepper, 1973). But the major difficulty may be that the self-perception changes that follow a person's initial compliance with a small request have never been clearly specified and may be much more complicated than has been acknowledged.

First, it may be unreasonable to expect the subjects' general perception of themselves to be altered by the kinds of brief experiences involved in these foot-in-the-door studies. In fact, particular subjects may only come to infer something about their attitudes or motives for a fairly limited set of situations (e.g., telephone solicitations from strangers). This notion is consistent with recent statements of self-concept theory (Gergen, 1971;

McGuire & Padawer-Singer, 1976), which emphasize that a person may harbor a variety of self-definitions that differ in salience across various situation contexts.

Second, measurement of these supposed changes in self-perception is made difficult by the fact that individuals are likely to code their behavior along different dimensions or into different groupings (Bem & Allen, 1974). Which behaviors constitute actions that are psychologically similar to the initial act of compliance is a function of each person's view of the world. To give one example, some persons might code their behavior as *compliance* or as *participating in a survey,* whereas others might code it as *helping someone in need.*

For these two reasons, investigators who have hoped to show a general change in subjects' self-definitions seem to have had little chance of success. Still, two experiments have successfully demonstrated that extrinsic incentives for help giving can lead helpers to describe themselves as less altruistically motivated. During the course of an experiment on "first impressions," Batson, Coke, Jasnoski, and Hanson (1978) asked male undergraduates to help an experimenter code data. Payment for this help was offered before subjects agreed to help (payment condition), after the subjects' agreement (payment after), or payment was not mentioned at all (no payment). The request for help was always made in the presence of a male confederate who never volunteered his services. A control group received no such request. Subjects were then asked to rate themselves and the confederate on several dimensions, including helpfulness and cooperativeness. As expected, subjects who agreed to aid the experimenter in exchange for money rated themselves as less altruistic than the confederate, whereas subjects in the other three conditions rated themselves as more altruistic.

In an experiment conducted by Smith, Gelfand, Hartmann, and Partlow (1979), second- and third-grade children played a marble drop game in which they could earn pennies toward the purchase of a prize. During the first part of the experiment, the children were given a number of opportunities, signaled by a light, to donate pennies to another child playing the game in a nearby room. The experimenter also created situations in which the children could not make a donation (but would think they should have done so) by having the signal light go off before they could respond. Whereas some subjects were merely praised each time they donated a penny, others were given a monetary reward for doing so, and the relationship between their help giving and the reward was spelled out to them. Other subjects were scolded by the experimenter each time they did not avail themselves of an opportunity to help; another group of children were fined each time they failed to donate, and the contingency between their behavior and the punishment was made explicit. Finally, a control group did not receive any type of reward or punishment from the experimenter. Intensive interviews conducted by a second experimenter with each subject showed that children who were rewarded or fined were more likely to attribute their help giving to external pressures than were children in the control group or than were those who received praise or a scolding.

Alternative Explanations for the Foot-in-the-Door Effect

Surprisingly few alternative explanations for the foot-in-the-door effect have been suggested. In part, this is because the self-perception analysis has proven to be a heuristic explanation, leading investigators to examine a wide variety of phenomena such as overjustification effects and the impact of social labels. Other explanations have not generated much research, but they do resurface periodically. Three of these are considered.

Adaptation Level

It has been argued that the small initial request to which people agree establishes a new baseline against which the subsequent larger request is compared (e.g., Schmidt, 1973). In other words, the prior request causes the magnitude of the second to be redefined, making it seem less extreme than it

otherwise would. It is not clear that this explanation would lead one to predict a difference in subsequent compliance between those who refuse and those who agree to the initial request. The perceived relative size of the second request should not depend very much on whether people have complied with the first request. However, several experiments show foot-in-the-door effects to be stronger when those who refuse the first request are excluded from the data analysis (e.g., Snyder & Cunningham, 1975; DeJong & Musilli, Note 3). It should be noted that this explanation cannot easily account for the results of studies looking either at extrinsic justification for the initial act of compliance or at the impact of social labels.

To lay this explanation permanently to rest, two types of studies could be done. First, subjects could be asked to rate the relative size of various requests under differing experimental conditions. Second, the subsequent compliance of those who are merely informed of a request being made of others and those who actually comply with that request could be compared. An adaptation level explanation would predict higher compliance from both of those groups, compared with a control group never before contacted, but self-perception theory would not.

Salience of Social Norms

Harris (1972) suggested that being asked to perform an initial small request makes people more aware of the norm of social responsibility, a norm that prescribes that one should help those who are in need. Like the adaptation level explanation, this argument also leads to the prediction that those who are only informed about the first request will be more compliant with the second demand. It would also lead us to expect a high rate of compliance from those who refuse the initial request, in contrast with available evidence. The major problem with this explanation, however, is that it, too, cannot account for the studies on extrinsic constraints or labels, which are better handled by the self-perception analysis.

Behavioral Consistency

It has also been argued that foot-in-the-door demonstrations show that people try to act consistently with the way they have behaved in the past. Does a person induced to agree to a first request agree to a second in order to sustain a consistent public image? If the effect were due to subjects' attempts at such impression management, then a larger foot-in-the-door effect should result when the second request is made by the same experimenter or involves the same issue or action. The importance of these kinds of variables has not been adequately tested, but the available evidence suggests that similarity between the requests on these dimensions is not terribly important (e.g., Freedman & Fraser, 1966).

A second version of this argument was suggested by Brock (1969), who argued, in essence, that people desire to be psychologically consistent for the sake of a self-image, not a public one. People have behaved in a certain way in the past and continue to behave that way in the future simply because they value consistency. However, it is clear that to manage a self-image in the fashion Brock suggested, people must first code their behavior and understand its attributional meaning. They must decide, essentially, whether the behavior reflects the pressures of extrinsic constraints or reflects their own dispositions or attitudes. Of course, it may be that the self-rewarding consequences of being consistent with one's self-image are what mediate the relationship between changes in self-perception and subsequent behavior. Evidence on this point is lacking.

Conclusions

1. It is concluded that the foot-in-the-door effect can be reliably obtained. Although the number of studies that have failed to demonstrate it unequivocally is surprising, it must be reemphasized that almost all of the studies reviewed showed experimental results in the predicted direction. Furthermore, a number of plausible explanations for failures to replicate can be offered.

2. In addition to the self-perception explanation first offered by Freedman and Fraser (1966), three alternative explanations for the effect have been suggested. It is concluded that these explanations are inadequate accounts of the foot-in-the-door literature.

3. A number of theoretical derivations from the self-perception explanation of the foot-in-the-door effect have been outlined, and the evidence for most is found to be generally supportive. However, investigators have not clearly specified the exact nature of the self-perception changes that are said to mediate the foot-in-the-door effect. Self-perception theory must concern itself with how people classify or code their own behavior and how they are led to form a broad or highly specific inference about their attitudes, traits, or dispositions. Echoing Bem's (1972) admission, it must also be underscored that self-perception theory does not fully explain the link between self-attribution and subsequent behavior. Further work is needed to explore these gaps in the self-perception analysis of the foot-in-the-door effect.

Salience and the Cognitive Mediation of Attribution

Eliot R. Smith
Department of Sociology
University of California, Riverside

Frederick D. Miller
New York University

Two studies of the impact of salience and informational factors on attribution and memory yielded findings on two general issues. First, manipulations of the amount of thought subjects gave to their attributions and of a delay before responding to attribution questions did not diminish the effect of salience on attribution; in fact, the delay increased the effect. Second, recall of the stimulus material was shown to be influenced by salience and by covariation information (consensus, distinctiveness, and consistency) and to be related to attributions. These findings, together with theory and data from the literature on comprehension and representation of linguistic material in memory, are used to argue that salience is not simply a process by which people make attributions without giving much thought to them. Instead, salience effects reflect the close relationships among the processes of comprehension, remembering, and attribution, and the fact that attributional processing can take place at the time of the encoding and storage of information, as well as at the time of its retrieval from memory.

The literature on the perception of causation currently contains support for two distinct and even opposed theories of the attribution process. Kelley (1967, 1972) has proposed that the perceiver makes attributions after logically weighing information about the covariation of an effect with various possible causes. This covariation information may be observed or assumed (Kelley's, 1972, "causal schema"), but in either case it is processed more or less rationally, in a fashion resembling the analysis of variance (ANOVA). Kelley's model of attribution has come to be known as the ANOVA model for this reason. On the other hand, several recent writers (Pryor & Kriss, 1977; Taylor & Fiske, 1975, 1978) have argued that perceivers use a much simpler information-processing strategy: attributing causality to the most salient plausible cause instead of weighing many possible causes to make a decision. Salience is used synonymously with Tversky and Kahneman's (1974) use of "availability" to suggest some factor that is literally prominent in the perceiver's field of view (Taylor & Fiske, 1975) or that is easily retrievable from memory (Pryor & Kriss, 1977).

A variety of studies have demonstrated that both object salience and the information specified by the ANOVA model *can* influence perceivers in making causal assignments. Taylor and Fiske (1978) present strong evidence that in many everyday situations perceivers give little thought to issues of causation, making attributions to salient stimuli off the "top of the head." These situations are primarily routine ones that involve the perceiver very little. On the other hand, in psychological experiments where information is available and instructions (or implicit demands) urge the subject to consider evidence carefully before making a response, perceivers can respond to information in the fashion Kelley suggests (McArthur, 1972).

The authors are grateful to Susan T. Fiske, Reid Hastie, and Shelley E. Taylor for their comments on an earlier version of this paper. The research reported here was supported by the University of California Academic Senate.

Requests for reprints should be sent to Eliot R. Smith, Department of Sociology, University of California, Riverside, California 92521.

Copyright 1979 by the American Psychological Association, Inc. 0022-3514/79/3712-2240$00.75

Is it possible to identify the processes by which both salience and the types of information identified by Kelley influence attributions? That is, going beyond the simple demonstration that different manipulations do influence attributions, research can address the question of how they do. One line of research that may give insights into processes is that aimed at identifying points of demarcation between salience and ANOVA processes (cf. Taylor & Fiske, 1978, Section VII). One prediction is that salience effects might weaken or vanish, and the more thoughtful ANOVA processes take over, when the attributor is highly involved in the situation about which he or she is making causal judgments. Taylor, Crocker, Fiske, Sprinzen, and Winkler (1979) attempted to moderate salience effects on attributions by a variety of manipulations. In several studies they varied distraction, general arousal, and interest in the event to be attributed—all ways of affecting the subjects' degree of involvement in the situation—but were unable to modify the salience effect strongly. This suggests that involvement in events may not lead to more rational, ANOVA-like processing of them; on the contrary, such engrossment may sometimes prevent more active processing. One can readily imagine a harried attributor tossing off causal judgments as needed in response to minimal cues. Study 1 of this article attempted to manipulate the subjects' degree of involvement in attributional *information processing* itself, as distinct from involvement in the *situation*, to determine whether salience effects are weakened when perceivers are forced to give extensive consideration to many possible causes, that is, under conditions that ought to be ideal for the emergence of the more rational information processing described by Kelley's ANOVA model.

The manipulation of salience used in this study was used and validated by Pryor and Kriss (1977). Their Study 1 showed that varying the order of the person and object in a sentence influenced the salience of each word: Specifically, the first-presented sentence element was identified more quickly in a reaction time task. The more salient word was more available in memory. Their Study 2 then showed that this salience manipulation, applied orthogonally to an information manipulation (sentences varying consensus, distinctiveness, and consistency), did affect attributions in the predicted direction. The more salient sentence element (person or object) attracted more attributions from subjects. It can be argued, however, that Pryor and Kriss's (1977) procedure, in its use of simple closed-ended attribution scales as the dependent measures, encouraged subjects to make quick, relatively unthinking attributions and hence encouraged reliance upon the salience cue. The current study focused upon this possibility. This study also examined recall data that may illuminate the processes that underlie the effects of salience and informational factors on attributions.

The present Study 1 conceptually replicates and extends Pryor and Kriss's (1977) Study 2. Pryor and Kriss presented subjects with 16 sentences of the type "Joe likes the film." In a within-subjects experiment they manipulated salience (by varying the order of presentation of subject and object in the stimulus sentence), information (by including additional sentences that contained consensus, distinctiveness, and consistency information pointing to either the subject or object as causal), and verb form (the verb was "like" or "dislike"). They measured attributions of causality to the subject and object on separate 11-point scales but reported analyses only on the difference between these two attributions. The current study largely followed Pryor and Kriss's procedure, with the addition of a between-subjects manipulation intended to influence strongly the amount of time and attention subjects gave to consideration of several possible causes in answering the attribution dependent measures, and a recall measure, administered after the conclusion of the attribution questionnaire, in which subjects attempted to reproduce the stimulus sentences.

Three specific predictions are made for this study.

1. Salience phenomena have been viewed as characteristic of perceivers who give attributional responses on the basis of a quick, sketchy analysis because they are uninvolved

—or are overly engrossed and pressed for time. This view implies that increased thought or information processing concerning attributions should diminish the effects of the salience manipulation.

2. If salience effects are mediated by cognitive availability or similar factors that affect memory, then relationships between attributions and memory should appear. Differential availability of the subject and object of the sentence should influence the way the sentence is recalled as well as the attribution that is made. In general, relationships between memory and attribution should provide information about the cognitive dynamics of salience.

3. Finally, the recall measures may be influenced by the manipulations (salience and information) that are applied to the sentences and are known to affect attributions. Effects of salience on recall would confirm once again (as in Pryor & Kriss's Study 1) that salience operates through an effect on the stimulus sentence's representation in memory (thereby influencing its recall). Effects of covariation information on recall are a more interesting possibility; they would point to a close connection between attribution and the cognitive processes involved in sentence comprehension and recall.

Study 1

Method

Overview. The first study replicates Pryor and Kriss's Study 2, extended in three ways. The first extension is the addition of a between-subjects manipulation intended to influence the amount of thought subjects give to their attributions. Subjects in the little thought condition received the closed-ended dependent measures used in the Pryor and Kriss study, two 11-point scales for attributions to the subject and object of the stimulus sentence (wording was, "To what extent was the given situation caused by [name of person or object]?"). Subjects in the moderate thought condition were instructed to think of and write in their own words one explanation for the event presented in the stimulus sentence and then to code that explanation using the two scales. Subjects in the extensive thought condition were asked to think of and write several (as many as five) different possible explanations for the given event, to consider them all carefully, to indicate the best explanation and, finally, to code that cause using the two closed-ended scales. A larger amount of careful and systematic thought should be given to the final closed-ended responses in the moderate and extensive thought conditions than in Pryor and Kriss's little thought condition.

The second extension is the addition of a recall measure. After subjects completed the experimental booklet that presented the 16 sentences and causal measures, they were given a sheet of paper with instructions to "list below as many [sentences] as you can remember—just the sentences, not the additional information that was given." Each sentence was coded for whether it was recalled with subject first or object first (paralleling the salience manipulation) and whether the subject and object of the sentence were each recalled.

The third extension is of a minor nature. Eight different positive verbs and eight different negative verbs were used in place of Pryor and Kriss's two verbs "like" and "dislike." This was intended to provide confirmation of their unexpected finding of a Verb Form × Information interaction.

Subjects. The subjects were 84 undergraduate and graduate students[1] (28 randomly assigned to each of the three conditions) at the University of California, Riverside, who were paid for their participation. Subjects were run in groups that were heterogeneous as to experimental condition and in which communication among subjects did not take place. The experimenter who administered the questionnaire and debriefed the subjects was blind to subjects' conditions.

Materials. Sixteen verbs were used in sentences, 8 different verbs implying a positive relationship between the subject and object of the sentence (e.g., likes, agrees with, is pleased with, helps, values), and 8 different negative verbs (e.g., dislikes, despises, complains about, is angry with). With this exception, the salience and information manipulations are as described by Pryor and Kriss (1977). Salience refers to the order of presentation of the subject and object, and information to the consensus, distinctiveness, and consistency factors presented in the same manner as in McArthur (1972). The salience manipulation is not equivalent to active versus passive syntactic forms of the sentence, although it does overlap somewhat. Some sentences (such as the first example below) are syntactically passive in the person-salient version (e.g., "Penny is disgusted by the turnips . . .") and active in the object-salient version (as shown). Examples are (object salient with object information):

The turnips at dinner disgust Penny.
The turnips at dinner disgust almost everybody.
Most other vegetables do not disgust Penny.
In the past the turnips at dinner have almost always disgusted Penny.

---

[1] The five graduate-student subjects were all from fields unrelated to social psychology, and exclusion of their data does not materially affect the results.

(person salient with person information):

Phil complains about his co-worker's habits.
Almost nobody else complains about Phil's co-worker's habits.
Phil complains about almost everybody's habits.
In the past Phil has almost always complained about his co-worker's habits.

(object salient with person information):

The vegetables at the Italian restaurant are liked by Tony.
The vegetables at the Italian restaurant are not liked by almost anybody else.
Most other vegetables are liked by Tony.
In the past the vegetables at the Italian restaurant have almost always been liked by Tony.

The salience, information, and verb form (positive/negative) manipulations were all orthogonal, forming a $2 \times 2 \times 2$ design of which each subject completed two entire replications, for a total of 16 different sentences. Four questionnaire forms were used, so that each stimulus sentence was presented to equal numbers of subjects in each of the four Salience $\times$ Information conditions. The order of presentation of the 16 sentences was randomized separately for each subject to avoid systematic order effects. The dependent measures (attribution and recall) were described above.

Results

The results fall into three sections: attributions, recall, and relations between attribution and recall. Attributions and recall were analyzed in a Thought $\times$ Salience $\times$ Information $\times$ Verb Form $\times$ Replication ($3 \times 2 \times 2 \times 2 \times 2$) analysis of variance, with all but thought being within-subjects factors. Replication is always treated as a dummy factor, and any significant effects it may have are ignored; it has no significant interactions that qualify effects discussed below.[2]

Attribution measures. The attribution dependent measures were subject attribution, object attribution, and the difference between them (the measure used by Pryor & Kriss, on which a higher score means more person attribution). In the current data, the within-conditions correlation between subject and object attribution averages $-.470$, $p < .05$, justifying the use of the difference score. In addition, results for all three measures are quite similar.[3] Considering the difference measure, four significant effects appeared, the first three of which were also obtained by Pryor and Kriss.[4] Covariation information strongly affected attributions: The mean attribution score was 5.08 with person-oriented information and -1.74 with object-oriented information. (Fs are shown in Table 1.) Salience also had a significant effect on attributions. The mean was 2.03 when the sentence was presented with the person salient and 1.32 when the sentence was presented with object salient. A significant Verb Form $\times$ Information interaction also appeared, with covariation information having more impact when the verb was negative than when it was posi-

---

[2] The use of an alternative analysis based on quasi F ratios, recognizing that replication as well as subject is a random factor in the design, does not change the essential conclusions. In the current study, subjects contributed much more variance than replications. The analyses reported here are ordinary Fs based on the appropriate interactions with subject as error terms, because this approach is more familiar and because in some analyses to be reported, the use of dichotomous scores renders untrustworthy the high-order interactions required for the computation of quasi Fs.

[3] The results for the object–attribution dependent measure were the same as for the difference measure, except that the effect of verb type was not significant. The results for the person measure were the same, except that the salience effect was only marginally significant ($p < .06$) and a three-way Verb Type $\times$ Salience $\times$ Information interaction reached significance, indicating that with negative verbs, object information and especially object salience gave rise to much less person attribution. The results for the difference measure thus summarize well the results for the two separate dependent variables: Four of the five significant effects on the difference measure (all except verb type) are at least marginally significant on both the person and object measures.

The strength of the person–object attribution correlation, in contrast to the typical findings of a nonsignificant correlation between measures of situational and dispositional attributions (e.g., Miller, Smith, & Uleman, Note 1), may be due to the presentation of the informational manipulations. These sentences strongly imply a person or object attribution for each stimulus sentence and hence may sensitize subjects to the idea that person and object attributions are alternatives.

[4] Verb form also affected attributions, with more person attributions being given for positive than for negative verbs. The Verb Form $\times$ Replication interaction was significant, however, so the verb form effect should be interpreted with caution (and it receives no further attention in this article).

Table 1
Analysis of Variance Results for Difference Attribution Measure and Significant Effects in Study 1

Effect	*MS*	*df*	*F*	*p*
Salience	170.715	1	6.556	.013
(Error) Salience × Unit	26.038	81	—	—
Information	15,614.238	1	205.811	.000
Information × Thought	435.421	2	5.739	.005
(Error) Information × Unit	75.867	81	—	—
Verb Form × Information	435.435	1	13.761	.001
(Error) Verb Form × Information × Unit	31.642	81	—	—

tive (means appear in Table 2). This replication of Pryor and Kriss's finding on verb form with an extended sample of verbs increases confidence in the effect. This interaction may be due to subjects being more careful (i.e., paying more attention to information) in their attributions for negative events, perhaps because such events have bad implications or are unusual (cf. Kanouse & Hanson, 1972).

The other attribution effect involved the between-subjects manipulation and so was not part of Pryor and Kriss's findings. The thought manipulation was successful. Subjects in the extensive thought condition wrote down and considered a mean of 3.1 different explanations before selecting the best. Subjects in the moderate thought condition wrote down one explanation and then coded it, whereas subjects in the little thought condition had only to make two checkmarks on closed-ended attribution scales. It is notable that the data contain no support for Prediction 1, which called for the weakening of salience effects in the extensive thought condition; for the Thought × Salience interaction, $F(2, 81) = .78$, $p = .46$. Salience effects on attributions were as strong when subjects carefully considered several possible explanations as when they simply made two checkmarks on attribution scales. The thought manipulation did interact with information, however, with the impact of covariation information being largest in the little thought condition and smallest in the extensive thought condition. Means appear in Table 2, and *F* test results in Table 1.

Table 2
Means of Difference Attribution Measure for Study 1

Item	Information	
	Person	Object
Thought[a]		
Little	5.683	−2.638
Moderate	5.839	−1.705
Extensive	3.723	−0.862
Verb form[b]		
Positive	4.860	−0.818
Negative	5.304	−2.652

Note. A higher mean indicates more person attribution and less object attribution.
[a] $n = 224$ observations per mean.
[b] $n = 336$ observations per mean.

Recall measures. Four recall measures were analyzed. These were the proportion of sentences recalled with person first, the proportion recalled with object first,[5] the proportion of persons recalled at all, and the proportion of objects recalled at all. Partial recall was fairly frequent, especially of the form "____ complains about his co-worker's habits." This example would have been scored as recalled

[5] These two proportions are independent, as they add to the proportion of sentences recalled at all, and not to 1.0. The order-of-recall variables were scored independently of the initial salience (i.e., order of presentation) of the sentences—that is, any recall of a sentence in a particular order was counted, not just correct recall of order.

with person first, object recalled, person not recalled. The reliability of this coding was near perfect. A second rater checked approximately 30 sentences, with no disagreements on coding.

Both salience and information influenced the order of recall variables. More sentences were recalled with the object first when the object was salient ($M = .125$ vs. .029), $F(1, 81) = 28.31$, $p < .001$. A Salience × Verb Form interaction affected both of the order-of-recall variables. Object salience led to stronger object-first recall, and person salience led to stronger person-first recall, when the verb was negative as compared with positive; for person-first recall, $F(1, 81) = 4.82$, $p < .05$; for object-first recall, $F(1, 81) = 5.66$, $p < .01$.

More important is an interaction of salience with covariation information. Inspection of the Salience × Information interaction means (Table 3) reveals that information has little or no effect on order of recall in the person-salient condition, where nearly all recalled sentences were reproduced accurately with person first—in this condition the mean object-first recall was only .029. When sentences are presented with object salient, however, there is more variation in the recall measures, and covariation information has an effect. For the Salience × Information interaction, for person-first recall, $F(1, 81) = 7.16$, $p < .05$; for object-first recall, $F(1, 81) = 9.16$, $p < .01$. Tests of the simple effects of information within the object-salient condition, using the appropriate pooled error mean square (Winer, 1970, pp. 544–545), reveal that this effect is significant for both the person-first recall and object-first recall measures, $t(81) = 3.07$, $p < .01$, and $t(81) = 2.93$, $p < .01$, respectively. In both cases, covariation information influences recall in the predicted direction, with the factor the information pointed to as the cause more likely to be recalled first. The clear conclusion is that these recall measures suffer respectively from a ceiling effect and a floor effect in the person-salient condition, producing the observed Salience × Information interaction. When the analysis is focused on the object-salient condition in which the absence of ceiling and floor effects allows the recall measures to show more variance, the effects of the covariation information manipulation on recall are significant.[6]

Table 3
Means for Recall of Verbs by Salience and Information for Study 1

Proportion recalled	Information: Person	Information: Object
Person salient (person first)		
Person first	.426	.459
Object first	.047	.012
Object salient (object first)		
Person first	.470	.358
Object first	.098	.152

Note. Each proportion is based on 336 observations.

Correlations between attributions and recall. Finally, we come to the relationships between attributions and recall. These were analyzed as partial correlations to ensure that a true relationship between the variables is present, not a spurious relationship resulting from the variables being affected in similar ways by the manipulated factors (cf. Taylor & Fiske, 1978, section VI.C). The partial correlations of the two attribution measures (person and object) with the four recall measures were computed across responses, controlling for salience, information, and experimental conditions (thought). This test shows

[6] Other effects on recall measures, not of central theoretical significance, can be briefly mentioned: More sentences were recalled person first, and more persons were recalled, in the extensive thought condition than in the other two conditions, $F(2, 81) = 4.54$, $p < .05$. Person recall was influenced strongly by verb form, with more persons presented with positive verbs being recalled (means of .317 vs. .208), $F(1, 80) = 19.05$, $p < .001$. The proportion of objects recalled was influenced by salience, with more object recall when the object was salient, $F(1, 80) = 5.95$, $p < .05$. Both object recall and person-first order of recall were influenced by a three-way interaction of Thought × Verb Form × Salience. However, this effect appears not to be simply interpretable and does not qualify the interpretation of any other significant effects, and it will not be discussed further.

that two of the eight relationships are significant. (The probability of obtaining at least two of eight relationships at the .05 level under the null hypothesis is less than .002 by a binomial test.) The proportion of sentences recalled object first was associated with attributions to the object on the object attribution scale, partial $r(1317) = .08$, $p < .01$, and proportion of persons recalled was associated with higher person attribution on the person scale, partial $r(1317) = .06$, $p < .05$. Thus, relationships between attribution and recall measures do appear when the experimental manipulations are controlled. The small size of these correlations can be attributed to the facts that (a) the attributional measures may be of low reliability (the two items only correlate .47) and (b) these are correlations between a continuous variable and a dichotomy, which can limit the maximum size of correlation coefficients to substantially less than 1. (Correction of these correlations for the attenuation due to the use of a dichotomy yields estimates of .15 and .08 for their "true" sizes, respectively; Harshbarger, 1977, p. 440.)

Discussion

Three basic findings were replicated in this study, and two new relationships were uncovered. Salience affects both recall and attribution, and covariation information affects attribution, as Taylor and Fiske (1975) and Pryor and Kriss (1977) have shown. In addition, information affects recall, in the object-salient condition where the recall measures showed adequate variance. Also, a partial correlation between recall and attributional measures emerged (controlling for the experimental factors).

Contrary to Prediction 1, thought (the extensive thought condition compared to moderate and little thought conditions) did *not* diminish the effects of the salience manipulation: no Salience × Thought interaction appeared. This supports the findings by Taylor et al. (1979) that salience effects remain robust despite a wide variety of manipulations. Rather than minimizing the effects of salience, greater thought appears to decrease the importance of the covariation *information* manipulation. The extensive thought manipulation was specifically intended to influence subjects to consider several explanations and choose the best one, rather than to engage in simple "top of the head" processing of just one causal possibility—the most salient one. The manipulation was evidently successful, as subjects in the extensive thought condition considered a mean of 3.1 different explanations. Yet the impact of salience was not reduced by the manipulation. A couple of points should be made about the thought manipulation. First, the particular manipulation used does not artifactually bias subjects to give more or less weight to any particular kind of information as a determinant of causal attributions (e.g., the covariation information); it asks them only to choose the best cause in the light of all available information. However, the manipulation may have other effects besides the intended one. For example, there may be a motivational effect: In the extensive thought condition subjects may have perceived the task as more important (since they were asked to spend so much time at it) and as a result may have tried harder to be accurate in their attributions. Still, the earlier theory of salience (as based on unthinking top-of-the-head responses) would predict that such a motivational effect would also reduce the impact of salience—contrary to what was found. The thought manipulation thus seems adequate to support the conclusion that we wish to draw from it: Salience effects persist even when subjects give careful consideration to many possible causes of an event.

The fact that salience manipulations have an impact over a broad range of conditions indicates that salience is not just a matter of making attributions without thinking. Instead, salience effects appear to be related to such cognitive processes as the way the stimulus sentence is perceived and encoded in the first place, giving rise to the observed memory–attribution links. These links are both the effects of information on recall (implicating attribution processes in the comprehension and recall of sentences) and the partial correlations between recall and attribution indices.

A simple model can account for the findings. In carrying out the experimental task, subjects must first comprehend the stimulus materials, then report their attribution, then (in the recall task) report their memory of the sentence itself. Results of Study 1 show that salience and information affect *both* the attribution and recall results and also that there is a partial correlation between attribution and recall indices. These effects can most parsimoniously be accounted for by the hypothesis that attributional processing and recall both operate from a single internal, encoded representation of the stimulus sentence to which the subject refers in answering the questions he or she is posed. The experimental factors that affect both attribution and recall can thus parsimoniously be assumed to affect the nature of the internal representation and thereby, indirectly, the dependent variables. It is easy to see that salience may affect the way a sentence is encoded, but the hypothesis that covariation information does so as well is novel. It has been generally assumed that such informational manipulations affect attribution but do not affect memory per se (Pryor & Kriss, 1977; Taylor & Fiske, 1975). Here, however, information is shown to affect recall, so parsimony suggests that the information factor too may operate through an effect on the representation of the sentence in memory. This proposition will be further tested in Study 2.

The subject's reporting of the attribution could then take place in either or both of two ways. The subject could retrieve from memory an attribution that was made during encoding and report it, *or* the subject could retrieve a representation of the sentence as well as of the additional consensus, distinctiveness, and consistency information and make a causal judgment at the time of retrieval. This argument that attributions are sometimes made at the time information is stored in memory, rather than subsequently on the basis of data retrieved from memory, has two noteworthy implications. First, as mentioned above, it is contrary to Pryor and Kriss's (1977) interpretation of salience. They raise two arguments against the idea that attributions are encoded and retrieved from memory: Since their subjects were not told that the experiments involved an attribution task they had no reason to make attributions; and covariation information did not influence the speed of recall in their study, as would be expected if attributions were involved in information encoding and storage. In response it can be argued that (a) social psychologists have often claimed that attributions are frequently made by people in their everyday lives, not just when experimenters ask for them. If we did not believe this, there would be little point in studying attributions. (b) Subjects in the Pryor and Kriss study, as well as in the current study, received the covariation informational manipulations with each sentence. Since these strongly point to either the subject or the object as the cause, it would be surprising if reading these stimuli did not generate some causal thinking. (c) In the current study, information was shown to influence two recall measures (not measures used by Pryor & Kriss).

Second, the notion that attributions can be made as information is stored in memory is consistent with many current theories of sentence comprehension and memory in cognitive psychology that give important places to inferred (attributed) causality. Among others, Kintsch (1974), Norman, Rumelhart, and the LNR Research Group (1975), and Schank (1975) have all proposed theories that involve the representation of "cause" links between propositions. In comprehending a text like "A burning cigarette was carelessly discarded. The fire destroyed many acres of forest," people make the attribution that the cigarette caused the fire and seem to store that inferred causal link as if it were explicitly stated in the text, when they are tested after a 15-minute delay (Kintsch, 1975). The cognitive theories and studies support the idea that attributional (cause-inferring) processing is intrinsically involved in the initial comprehension of sentences and therefore that it goes on all the time, not just when a subject is asked an attributional question. Such theories also imply that the cause generated by the initial attributional processing is represented in memory in some form. Hence relations between recall and causal responses,

such as those obtained in Study 1, are to be expected.

Our tentative model thus holds that subjects comprehend the stimulus material: They process the sentence as influenced by the salience and information factors and transform it into a representation in memory. Some attributional inferences occur in this process, and causal material is included in the memory representation (Kintsch, 1974, 1975). If subjects are immediately asked to give an attribution, they may report the cause they have stored in memory—but on the other hand, the additional covariation information may still be available to them, so subjects may be able to carry out further attributional processing in response to the question. If a delay intervenes between the study of the material and the attributional question, Kintsch's results suggest that subjects will be more likely to answer the question directly from the memory representation. The additional covariation information will in general have been lost from memory during such a delay. Only the stimulus sentence itself will be retrievable because it was more intensively studied by the subjects and because it is more central; such propositions are better recalled (Kintsch, 1974). The prediction of this model is thus for a stronger relationship of attribution and recall indices after a delay than immediately and for a greater influence of salience on attributions (via its influence on the memory representation) after the delay. These hypotheses parallel Kintsch's (1975) results showing that after a delay causal relations seem to be retrieved as part of a person's encoded memory for the event itself, not as separately encoded information.

Study 2 was conducted as a test of these ideas. In particular, it was predicted that (a) the effect of information on recall found in Study 1 should be replicated within the object-salient conditions where some variation exists in the order-of-recall measures; (b) the partial correlation of attribution and recall variables should be replicated; (c) this attribution–recall relationship should increase with time after the presentation of the sentences, since other information (e.g., the covariation information) should have decayed from memory and the subject will be forced to base his attribution and recall responses on the same encoded memory representation of the sentence (cf. Kintsch, 1975); (d) the effect of salience on attributions should also be stronger after the delay, since that effect is presumed to be mediated by the memory representation.

Study 2

Method

Overview. Subjects read sentences similar to those in Study 1, together with the salience and information manipulations, presented as materials for a study of memory. After studying the sentences for 8 minutes, some subjects (randomly assigned to the immediate condition) were asked to recall as many sentences as they could in 10 minutes, writing each one and then answering the two closed-ended subject and object attribution questions about it (essentially Pryor & Kriss's questions). During this time, the other subjects (those in the delayed condition) performed an irrelevant anagrams task. A 20-minute delay then followed, during which the subjects listened to and took notes on a lecture on an unrelated topic. Finally, the memory and attribution dependent measure was administered to all subjects, again for 10 minutes. Thus, immediate recall subjects filled out the measure beginning only seconds after they had finished studying the sentences, and delayed subjects filled it out 30 minutes later.

Subjects. The 107 subjects were volunteers drawn from introductory social psychology courses at the University of California, Riverside (26 subjects) and at New York University (81 subjects). The study was run during a class period, prior to exposing the students to material concerning attribution in the course.

Materials. The 16 sentences used in this study were written to have a person as subject and a nonhuman object, to eliminate ambiguity in the wording of the attribution questions (see below). Some sentences from the first study were retained and some new ones were written. The salience and information manipulations were as described for Study 1. In this study, to simplify the experimental materials and the task of balancing cell sizes in two locations 3,000 miles apart, sentences were nested within (Salience × Information), so that just one form of stimulus presentation needed to be prepared. That is, each sentence was presented in just one Salience × Information condition.

The dependent measure consisted of 16 occurrences of three questions: "Write down one of the sentences here, as exactly as you can remember it—just the sentence, not the additional information about it" (i.e., the information manipulation), followed by person and object attribution questions. These were the

same as those used in the little thought condition in Study 1, except that instead of including the person's name and the object from the sentence (which would have constituted a powerful recall cue for each sentence), the questions asked, "To what extent was the event described in the sentence caused by the *person* named in the sentence" and "caused by the *object* the person was reacting to."

Coding of variables. From the dependent measure, each stimulus sentence was coded as recalled with person first, with object first, or not recalled; the person was coded as recalled or not; and the object was coded as recalled or not. Four recall measures identical to those in Study 1 result. Since attribution measures are available in this design only for sentences that were recalled, analyses involving the attribution variables must exclude sentences that were not recalled. For such analyses the two order-of-recall variables are redundant (since a recalled sentence must be scored as either recalled person first or recalled object first) and only one can be used. The person and object attribution scales were used in their original form, with a higher score meaning in each case less person or object attribution. A difference score was not used in this study, since the correlation of the two attribution scales was only −.26, not strong enough to justify using the difference as a single summary measure.

Analysis. Attributions cannot be analyzed in a repeated-measures design in this study because they are not given for sentences the subject did not recall. Recall, however, can be so analyzed. The ANOVA design is Time × Sentence Nested Within (salience by information), the latter three all being within-subjects variables. Attributions and the relationships among recall and attribution variables can be analyzed with the sentence as the unit of analysis. Since a subject typically recalled several sentences, the observations in this mode of analysis are not independent of each other, giving rise to some degree of bias. The bias is small, however, since the variance due to sentences is generally many times greater than that due to subjects in these analyses, and this analysis is the most effective available for examining the questions of interest.[7]

Results

It was predicted first that this study would replicate an effect found in Study 1, an impact of information on the order of recall of a sentence, within the object-salient condition. Unfortunately, no such effect was found, and the reason became clear in examining the ANOVA table: The design used, with sentences nested within information, had very low power to detect such effects, since the sentence factor contributed much variance (sentence was significant at the .001 level for both the order-of-recall dependent measures). This indicates that the design should have crossed Sentence × Information Condition, as Study 1 did, yielding higher power for tests of information effects (cf. Kenny & Smith, Note 2).

The second prediction was for a within-conditions relationship between attribution and recall. This was examined by computing correlations between the three recall variables (order of recall, person recalled, object recalled) and the two attribution variables (person and object attributions) separately for the four combinations of Time × Salience. (Information need not be considered, since it did not significantly affect recall; thus, it cannot generate spurious correlations between recall and attribution measures.) One of the 12 correlations from the immediate subjects was significant: In the object-salient condition, object recall was associated with less person attribution, $r = .14$, $p < .05$. For the delayed subjects, 4 of 12 correlations reached the .05 level, all in the object-salient condition. All three recall variables (object-first order of recall, person recall, and object recall) were associated with more person attribution ($r = -.16$, $-.22$, and $-.17$, respectively). Object recall was also associated with more object attribution, $r = -.20$. Overall, obtaining 5 of 24 correlations at the .05 level by chance

[7] The use of analyses that may contain technical violations of assumptions has precedents in the attribution literature. McArthur (1972) found herself in a situation similar to ours, argued that the bias due to ignoring subject effects would be "negligible," and proceeded with an analysis that is conceptually similar to the ones we perform. Our data permit a reassurance like the one she was able to give: The correlation of recall responses given by the same subject is negligible relative to item effects. In addition, we have conducted reanalyses to test the effects of the violations of assumptions. Removal of subject effects from the attribution variables (by subtracting each subject's mean score from each observation) and reanalyses of these corrected scores show that the major points of the paper are unaffected by the nonindependence in the original data. This is the case with the partial correlations between memory and attribution in Studies 1 and 2, the ANOVA on attribution in Study 2, and the path models in Study 2. (The other analyses reported in the paper explicitly incorporate the subject variable and so are not subject to the criticism of nonindependence of observations.)

alone has a binomial probability of less than .002: a clear demonstration of relationships between recall and attributions.

The third prediction was that the relationship between recall and attributions should be stronger when recall was delayed. This issue can be illuminated by path diagrams showing the influences of the experimentally manipulated factors on recall and attribution variables, separately for the immediate and delayed recall conditions. Using the conventions of path analysis to draw the diagrams (Duncan, 1975), the following are the results for the most sensitive recall and attribution variables, object-first recall and person attribution.[8]

In Figure 1, the straight arrows represent the causal effects (numerically, the standardized regression coefficients) of the manipulated variables on the two response variables. The residual causes u and v represent all other causes of the responses (i.e., error variance). The curved arrow between u and v represents a correlation between those residual causes, generated theoretically by an unmeasured factor that has a causal impact on *both* recall and attribution (in this case, the factor is presumed to be aspects of the memory representation of the sentence). Note that the model shows neither the recall nor attribution dependent variables as causing the other. This is a consequence of the theoretical viewpoint sketched above: The recall and attribution processes must work from the same encoded representation of the sentence (so one can expect to find a partial correlation between them, represented in the diagram by the correlation between the residual causes u and v). However, neither can be presumed to cause the other, even though the recall dependent measure comes first in time—attributions (those made during the initial processing of the sentence) may influence recall as well as the other way around.

In the immediate condition, there seems to be a separation of the recall and attribution processes: Salience affects recall, and the informational manipulation affects attribution. Furthermore, the residual correlation between recall and attribution is nonsignificant. However, the delayed condition shows a different

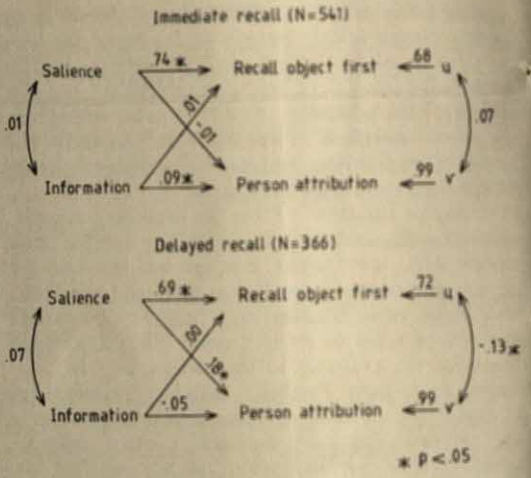

Figure 1. Path diagrams showing relations among manipulated factors, recall, and attribution in immediate and delayed conditions, Study 2. ($p < .05$.)

pattern of effects. Salience still strongly affects order of recall, but it now also affects attribution. The information effect has vanished. Finally, the partial (residual) correlation is now significant. (These three correlations or path coefficients differ significantly between the immediate and delayed conditions.) An

[8] Detailed results for the other combinations of variables are not presented here for reasons of space. Briefly, the object attribution measure never shows significant relations in these analyses, so only the person scale need be considered. There are three nonredundant recall measures, object-first recall, person recall, and object recall. (Since only sentences that are recalled have attributions, results using the person-first order-of-recall variable are identical to those with the object-first variable except for having the opposite sign.) The major conclusions are the following: (a) For two of the three analyses (object-first recall and person recall), the delayed recall-attributional correlation is significant and significantly different from the immediate one; (b) in all three cases, there is a significant delayed effect of salience on attribution, significantly greater than the immediate effect; (c) for object recall only, there is a significant delayed effect of information on recall—such that information implying that the object is causal leads (after the delay) to a greater likelihood of recalling the object. This effect supports our model but is not discussed further, since it appears with only one of the three measures. Researchers on salience, at least since Taylor and Fiske (1975), have often obtained theoretically expected effects with only a subset of dependent measures; the exact form of the most appropriate measure is a matter for further study.

analysis of variance on the person attribution variable verifies that the impact of salience is stronger after the delay: Salience × Time interaction, $F(1, 12) = 8.39$, $p < .05$.

Discussion

This pattern of findings lends support to the idea that after a delay (though not immediately after study of the sentences) recall and attribution are based on a single encoded representation of the sentence. The effect of salience on that encoded representation seems to be stronger than the effect of the information manipulation: the effect of salience on attribution was significantly stronger after the delay than before. On the other hand, the impact of information was significantly weaker (and nonsignificant) after the delay. This pattern may be accounted for by the salience manipulation's status as part of the sentence itself, whereas the covariation information was presented as separate sentences, subject to memory decay during the 30-minute delay.

Several puzzles remain in the results. First, the residual correlation between recall order and attribution in the delayed condition is in the wrong direction. That is, order of recall has a relation to attributions opposite to that of the order of presentation of the sentence. The reason for this is unknown; the exact form of the representations of sentences in memory is a matter of some controversy (cognitive theories differ widely on the issue). Similarly, we do not yet know what specific characteristics of the representation are responsible for observed differences in order of recall or attribution. Salience does appear to affect the memory representation, but the development of sensitive and relatively pure measures of the affected characteristics remains a topic for future research. Second, the recall–attribution partial correlations in Study 1, although significantly different from zero, were small. This may also be due to the use of measures that are only indirectly related to the true variables of interest, or the effects may actually be relatively small in magnitude (and thus difficult to study). In either case, the elucidation of the relationships among salience, attributions, and the cognitive processes and representations involved in sentence comprehension is a goal that deserves the further research efforts that will be required.

Conclusions

In summary, this article has attempted to accomplish three things. It has presented evidence that one effect of salience—the dependence of attributions upon the order of presentation of person and object in a stimulus sentence—is surprisingly robust. The effect holds up even when the subject is instructed to invent several possible causes and pick the best one and becomes *stronger,* rather than weaker, after a delay that forces subjects to rely more on an encoded memory. This finding led to the idea that salience processing involves more than just top-of-the-head responses but may reflect the basic cognitive processes underlying sentence comprehension and the storage of events in memory. (This analysis could be extended to visual manipulations of salience, as in Taylor & Fiske, 1975, by assuming a verbal representation of encoded visual material; cf. Chase, 1978.) One implication of the data is that strict lines of demarcation between salience processes and more thoughtful attribution processes do not exist. Rather, one must seek to understand how salience and informational factors exert influence on the perceiver across a series of stages of encoding, processing, and recall.

Second, two new findings concerning memory are presented (in addition to the replication and extension of Pryor & Kriss's finding that salience affects memory as well as attributions): an effect of information on recall (in Study 1) and a relationship between attributions and characteristics of the recall of a sentence (in both studies). Further research is clearly needed to investigate the effects of different types of stimuli and different delay periods and particularly to identify the most appropriate and sensitive recall measures with which to elucidate the cognitive processes underlying attribution. The present findings point to a close relationship between the processes that subjects use in reporting attri-

butions and in reporting recall; in particular, we advance the hypothesis that both of these processes work from an encoded representation of the stimulus that the subject initially forms. This interpretation is supported by the fact that both the recall–attribution relationships and the effects of salience are increased by a delay (Study 2). Although the support of the hypothesis by these findings is inferential, theory and data from the literature on text comprehension and representation, cited earlier, also argue strongly for such an encoding process, which can involve attributional processing at the time of the encoding and storage of a stimulus as well as at the time of its retrieval. Thus attribution can mediate memory, as well as memory mediating attribution.

Third, an implicit message of these arguments has been that the formulation of explicit theories of information processing in an experimental task can be a productive approach for future research. Instead of asking about whether one variable mediates another in the sense that a statistical relationship between them can be established, we should attempt to understand how the subject goes about performing the task and therefore how the results of a process such as encoding or memory can influence other subsequent processes. Such explicit theories of stages in information processing lend themselves readily to test by means that have been used in cognitive psychology with great success for the past several years (Schneider & Shiffrin, 1977; Shiffrin & Schneider, 1977; Taylor, 1976).

Effects of "Voice" and Peer Opinions on Responses to Inequity

Robert Folger, David Rosenfield, Janet Grove, and Louise Corkran
Southern Methodist University

Two experiments investigated the effects of "voice" (participating in allocation decision making by expressing one's own opinion about the preferred allocation) on responses to an inequitable allocation. In addition to subjects' (female college students) either having or not having voice, Experiment 1 manipulated (a) whether the allocation made by a "decision maker" (supposedly another subject but actually the experimenter) was or was not biased (due to self-interest) and (b) whether the subject did or did not learn that a "co-worker" believed the allocation to be inequitable. Experiment 2 (with female high school students) manipulated the presence or absence of voice and involved only a self-interested decision maker; also, a note from a co-worker either supported the decision maker's allocation or confirmed the subject's opinion that the allocation was inequitable. In both experiments, the impact of voice was mediated by knowledge about the co-worker's opinion. When subjects had no knowledge of the co-worker's opinion (Experiment 1) or knew that the co-worker's opinion coincided with the decision maker's allocation (Experiment 2), there was evidence for a "fair process effect": Voice subjects expressed greater satisfaction than those with no voice.

How do people know that they have been treated fairly? According to equity theory (Adams, 1965; Walster, Berscheid, & Walster, 1973), a distribution of outcomes is considered fair (equitable) if the ratio of outcomes to inputs is constant across people. Apart from considerations of equity, however, fairness judgments may also be affected by whether a distribution is the result of an acceptable decision-making procedure (see the distinction between distributive and procedural justice in Folger, 1977; Leventhal, 1976; and Thibaut & Walker, 1975). Deutsch (1975), in discussing how "injustice of decision-making procedures" affects the perception of justice, makes the following argument: "There is much social psychological research which would suggest that . . . [procedural] injustice is the most fundamental. The research to which I am referring indicates that people are more apt to accept decisions and their consequences if they have participated in making them" (p. 139).

Indeed, many classic studies support Deutsch's position. Lewin, Lippitt, and White (1939), for example, found that the unity of a group was greater under democratic leaders than under autocratic or laissez-faire leaders. Similarly, Shaw (1955) found group members to be more satisfied under nonauthoritarian than under authoritarian leaders. Another classic example is Leavitt's (1951) research on communication networks, which found that the satisfaction of group members increased as the centrality of their position (opportunity to influence decisions) increased. Reviewing related research, Lawler (1975) concluded that workers' participation in decision making can lead to both greater worker satisfaction and higher productivity.

There is, however, an ambiguity in this research. Positive feelings may reflect the *consequences* of participation rather than par-

Preparation of this manuscript was facilitated by a National Science Foundation Postdoctoral Fellowship to the first author and by National Institute of Mental Health Grant 30968-01 to the first two authors. Philip Brickman graciously provided comments on an earlier draft.

ticipation per se (i.e., increased participation in decision making might ordinarily lead to people actually obtaining more favorable outcomes). Although those given an opportunity to make their preferences known can hope to influence the outcome, it is clear that they may at times be unsuccessful. It is important, therefore, to distinguish between (a) the response to an opportunity to exercise a "voice" in decision making (cf. Folger, 1977; Hirschman, 1970)[1] and (b) the response to the outcome of having exercised voice. A key issue is whether voice is in itself sufficient to induce greater acceptance of decisions that result in inferior outcomes.

Thibaut and Walker (1975) provide an encouraging answer to this question in suggesting that the opportunity to present evidence supporting one's own case (voice) has a remarkable effect on a defendant's satisfaction with the verdict. Their research has demonstrated (1975; see also LaTour, 1978; Walker, LaTour, Lind, & Thibaut, 1974) that the more such voice is available, the more an otherwise intolerable outcome (e.g., a guilty verdict imposed on those who think themselves innocent) becomes relatively acceptable.

We will refer to Thibaut and Walker's pattern of results as the *fair process effect*. This effect refers to cases in which greater satisfaction results from giving people a voice in decisions. Thibaut and Walker's results suggest that satisfaction with the procedure may also generalize to other aspects of the situation (e.g., the distribution of outcomes). Our investigation concerns the generality of the fair process effect, and we begin by examining an experiment that produced the opposite results —a pattern that we will term the *frustration effect*.

In a study by Thibaut, Friedland, and Walker (1974), each of four subjects was assigned the role of a "corporation" in an industrial simulation. A fifth participant, actually a confederate, was assigned the role of a "government" empowered to collect taxes according to one of two fiscal policies, one being fair and the other being inequitable (the following account pertains only to inequitable conditions). In the "participation" condition, the fiscal policy was allegedly determined by a vote of all participants (a voice procedure). Bogus feedback about this vote showed that two corporations had voted for the equitable policy and two for the inequitable policy and that the government had cast the tie-breaking vote that established the inequitable policy. In the "no-participation" condition, the government decided on the inequitable policy without consulting the corporations.

The results showed that the proportion of taxes paid to taxes owed was approximately twice as high among no-participation subjects as among participation subjects (i.e., those who had voice were *more* likely to express discontent with the inequitable policy by cheating on their taxes). Thibaut et al. explained these results, which are clearly opposite from a fair procedure effect, by suggesting that discontent is intensified whenever a participative process raises hopes for a desired outcome and those hopes are dashed.

Thus the proposed mechanism whereby voice can cause heightened displeasure is increased frustration due to raised expectations (hence the term *frustration effect*). But if voice enhances frustration when outcomes are inferior, why was the opposite, fair process, effect evident in the LaTour (1978) and Walker et al. (1974) studies, which involved unfavorable outcomes? One possible answer (Thibaut, Note 1) is that although the decision maker in these latter studies was a neutral or "disinterested" third party, the government in the Thibaut et al. (1974) study was clearly voting for its own self-interest. However, Folger (1977) found a fair process effect under some conditions in which the

[1] The original use of the term *voice* by Hirschman (1970) was in the context of alternative responses to declining outcomes. At the same time, however, a more general usage was suggested by passages such as the following (pp. 16, 30): "Voice is political action par excellence"; "voice is nothing but a basic portion and function of any political system, known sometimes as 'interest articulation.'" It is in this sense of interest articulation that we use the word *voice* in place of longer locutions such as "opportunity to express opinions and preferences or to present facts relevant to one's position in the context of decision making."

allocator did benefit directly from this inequity, as was the case in the Thibaut et al. study. Since this result demonstrates a fair process effect even when the allocator's self-interest could have biased the decision, it appears that some other aspect of the Thibaut et al. study was responsible for the frustration effect.

We suggest that the frustration effect in the study of Thibaut et al. was due to the feedback subjects did or did not receive about the other subjects' opinions. Since no vote was allowed in the no-participation condition, subjects in this condition did not know the fiscal policy the other corporations favored. In contrast, each subject in the participation condition learned that in addition to himself, one other corporation had opposed the inequitable policy; thus these subjects had social support for their opinions.

The importance of such social support is highlighted by Asch's (1952) conformity studies. When the majority's unanimity was broken by a single confederate, the ordinarily substantial rate of conformity was markedly reduced. Perhaps a similar phenomenon occurred when participation subjects learned that one other corporation agreed with their own opinion: This support from a solitary peer may have reduced these subjects' tendencies to conform to the government's opinion, thereby leaving them more dissatisfied with the inequitable result. Unfortunately, since voice and feedback about others' opinions were confounded in the Thibaut et al. experiment, it is impossible to determine which factor was responsible for the obtained effect. The present line of investigation involves two experiments designed to shed light on this issue by manipulating procedure and feedback independently of one another.

It is predicted that voice will interact with the feedback the subject receives concerning the other subject's opinion. The exercise of voice should lead to more positive responses when subjects do not receive any feedback from others supporting their own opinion that the decision was unfair, conditions similar to those that yielded a fair process effect in the LaTour (1978) and Walker et al. (1974) studies. However, when subjects receive information from others that confirms their beliefs and indicates that the final decision was inequitable (as in the Thibaut et al. study), then voice may not lead to a fair process effect. Additionally, Experiment 1 will include a manipulation of whether the decision maker is biased or unbiased. As noted above, Thibaut has suggested that voice may not lead to a fair process effect if the decision maker has some external inducement that might have biased his or her decision.

Experiment 1

Method

Subjects. The subjects were 82 female undergraduates enrolled in an introductory psychology course. They received extra credit for participating in the experiment. Although the gender was restricted primarily for convenience, it should be noted that previous research has suggested that females are more likely than males to prefer an equal division of outcomes (e.g., Leventhal & Lane, 1970).

Procedure. The participants, scheduled in groups of three, were seated in separate rooms and listened to taped instructions. They were told that the study was simulating business decision making and that a random drawing would assign subjects to the roles of "decision maker" and "workers" (each person was actually assigned the worker role). Workers were to make small words from the letters of a larger word and to help evaluate the decision maker's effectiveness. There would be two sessions of four word-making trials, and on each trial the decision maker would select from a list of words a subset that would be given to the two workers (making the selection so that the number of possible smaller words would be maximized). The subjects were also told that they would receive lottery tickets for a $50 prize as additional compensation. Nine tickets were to be distributed during each of the two work sessions, with three of those tickets going to the decision maker. The decision maker would decide how to divide the remaining six tickets between the two workers.

Subjects in the *unbiased* decision-maker condition were told that whoever drew the role of decision maker would keep that role for both work sessions, which meant that she would receive the same number of tickets regardless of how she chose to allocate the workers' tickets. In the *biased* condition, the person initially chosen as decision maker would have that role for one session only. During the second session, one of the workers would become the new decision maker and would be in a position to determine how many tickets the original, first-session decision maker would receive during the second session. Thus, the decision maker's ticket allocation during the first

session might be biased because she would have an extrinsic reason to favor one worker (the one who would be the next decision maker) over the other.

In all conditions, the drawing was rigged so that the subject believed that she would be a worker (Worker B) during both sessions. In the biased condition, she also believed that the other worker for the first session (Worker A) would be the decision maker during the second session. Note that subjects thought the initial decision maker knew which first session worker would be the decision maker during the second session (Worker A).

After the first session, every subject was asked to complete ("for our records") an "opinion card" on which she wrote her ideas of the fair way to divide the lottery tickets for that session. In the *voice* conditions, the experimenter then added the following statement:

> Even though the decision maker will be making the final decision about how the lottery tickets will be divided, one of you workers will have an opportunity to let her know what you think is fair before she makes her decision. We will have a drawing and the worker who wins the drawing will get to have her opinion card shown to the decision maker.

Subjects in the *mute* (no voice) condition were not given these additional instructions.

Before the subject filled out her opinion card, the experimenter counted the total number of smaller words that she had made (supposedly to be reported to the decision maker) and told the subject how many words the other worker had allegedly formed (one more than the subject's total). The experimenter then left, taking the opinion card with her in the voice conditions. The experimenter administered the feedback manipulation upon her return. Subjects in the *inequity-confirmed* conditions were told that the co-worker had suggested an even split of the six tickets, whereas the decision maker had chosen to give that co-worker four of the tickets and to give the subject only two. The information about the co-worker's opinion thereby reinforced the subject's feelings that a 3–3 split was fair and confirmed that the 4–2 decision was inequitable. Subjects in the *no-feedback* conditions were only told about the decision maker's allocation (a 4–2 split favoring the other worker). It should be noted that in the biased condition, the 4–2 split favored the worker who was to become the decision maker during the next session. Thus that decision could apparently have been due to the decision maker's desire to be treated favorably during the second session.

Subjects were then given a questionnaire to evaluate the effectiveness of the decision maker. Included were items concerning the subject's feelings about the fairness of the allocation and about the fairness of the decision-making process, each answered on a scale anchored by "very unfair" (1) and "very fair" (11). Another item assessed subjects' general satisfaction with the work situation on a scale ranging from "very dissatisfied" (1) to "very satisfied" (11). Finally, two questions asked the subjects to rate their decision maker on scales of "incompetent" (1) to "competent" (11) and "inefficient" (1) to "efficient" (11). Answers to these two items were summed to obtain an average rating of the decision maker.

After completing the questionnaire, the subjects were told that there was not enough time left to finish the experiment. The experimenter then attempted to assess any suspicions that the subjects had and debriefed them. The subjects were also told that they would each receive three tickets for the lottery. A lottery drawing actually took place at the end of the semester, and the winner was given her $50.

Results and Discussion

The results were analyzed by a $2 \times 2 \times 2$ multivariate analysis of variance. This MANOVA revealed that the Feedback (No Feedback vs. Inequity-Confirmed) × Procedure (Voice vs. Mute) interaction was significant, $F(4, 71) = 2.77$, $p < .05$. Also, the procedure main effect was marginally significant, $F(4, 71) = 2.07$, $p < .09$. Given these results, univariate analyses of variance (ANOVAs) were examined to determine the nature of these effects.

The univariate ANOVAs showed significant procedure main effects on the fairness of the process, the ratings of the decision maker, and the fairness of the allocation, $F(1, 74) = 7.45$, $p < .01$; $F(1, 74) = 4.30$, $p < .05$; and $F(1, 74) = 5.72$, $p < .05$, respectively. As Table 1 shows, subjects in voice conditions generally expressed more positive feelings than those in the mute conditions. Note, however, that the mute–voice differences are always larger within the no-feedback condition; these differences are generally quite minimal in the inequity-confirmed condition and are even reversed slightly on the satisfaction measure.

In fact, the procedure main effect is qualified by the significant Feedback × Procedure interaction, indicating that the main effect was due almost entirely to the large differences within the no-feedback condition. This interaction was significant on the univariate analyses of the fairness of the decision-making process and the subject's satisfaction with the work situation, $F(1, 74) = 5.34$, $p < .05$, and $F(1, 74) = 4.89$, $p < .05$,

Table 1
Responses to Inequity as a Function of Procedure and Feedback, Experiment 1

Measure	Inequity confirmed		No feedback	
	Mute	Voice	Mute	Voice
Fairness of the process	6.7	7.0	5.6	8.8
Fairness of the decision	4.9	6.4	6.0	7.8
Satisfaction	8.1	7.7	7.6	9.5
Ratings of decision maker*	14.6	15.3	15.0	18.4

* Higher numbers indicate more positive ratings of the decision maker.

respectively. As Table 1 demonstrates, voice did not lead to substantially more positive reactions than did mute in the inequity-confirmed conditions ($p > .50$ for each of the four dependent measures), but it did lead to substantially more positive feelings for those subjects who were given no feedback and hence were not as convinced that they had been treated inequitably ($p < .05$ for fairness of the process and satisfaction with the work situation).

This experiment thus substantiates that voice sometimes tends to mitigate the distress associated with inequitable treatment; however, the significant Feedback × Procedure interaction indicates that voice alleviates distress only when the subjects do not receive a second opinion from their co-workers suggesting that the co-workers also feel that the decision was inequitable. When such an opinion is received (which reinforces the belief that the decision was unfair), voice does not make the subjects feel that the inequitable decision was any more satisfying.

There was little evidence of any strong tendency for knowledge of a supportive opinion to make voice any *less* satisfying than the mute procedure, as it did in the Thibaut et al. study. However, it is possible that increased displeasure due to voice may be unique to situations in which decision makers stand to benefit directly from the allocation, as they did in the Thibaut et al. study. In our study, the decision maker could benefit indirectly in the biased conditions (if giving more lottery tickets to the worker who would be the next allocator would increase the chances of being overrewarded by her in return), but the indirect nature of this advantage may have reduced its salience, as is reflected in the absence of any significant differences between the biased and unbiased conditions. Since Experiment 2 placed the decision maker in a position to benefit directly from reducing the payments to other people, further discussion of frustration effects will be postponed until after the presentation of that experiment.

Experiment 2

Method

Subjects. In response to telephone solicitations, 61 female high school students participated. Each understood that she would receive at least the minimum wage for participating for 1 hour in a study about "working conditions."

Procedure. Experiment 2 was conducted similarly to Experiment 1, with several exceptions. First, there was no biased–unbiased manipulation (Experiment 2 used biased conditions only). During each work session, the decision maker supposedly had $3.00 to divide between herself and the two workers. Thus, by giving the workers less (her decision was allegedly to give the workers $.75 each), she was able to keep more for herself ($1.50). In keeping with this procedure, it was further announced that the decision maker would remain in that role for the entire experiment (three sessions).

Another difference was that the feedback manipulation was stronger. In the *inequity-confirmed* conditions, subjects were told that their co-worker had indicated on her opinion card that an even split of the $3.00 was fair. Since the decision maker supposedly gave the workers only $.75 while keeping $1.50 for herself, this feedback confirmed the subjects' feelings that the decision was inequitable. In the *inequity-disconfirmed* conditions, the subjects again received information about their co-worker's opinion, but this time the co-worker supposedly had indicated that $.75 for the workers and $1.50 for the decision maker was fair. Another difference between the first and second studies was that the decision maker in the latter was not told how many words the subjects had formed. Thus her decision was made (allegedly) without taking productivity into account.

The final difference involved dependent measures. In addition to the measures used in Experiment 1, Experiment 2 also asked subjects to indicate how certain they were that the division of money that they had written down on their opinion card (before learning about the decision maker's allocation or

Table 2
Responses to the Inequity as a Function of Procedure and Feedback, Experiment 2

Measure	Inequity confirmed		Inequity disconfirmed	
	Mute	Voice	Mute	Voice
Fairness of the process	5.5	4.9	6.2	8.7
Fairness of the decision	3.7	2.7	5.5	6.0
Satisfaction	7.3	6.7	7.1	7.7
Ratings of decision maker[a]	13.1	14.5	16.2	15.7
Payment to decision maker	79.7	70.3	85.7	107.0
Certainty	9.9	9.4	9.1	6.3

[a] Higher numbers indicate more positive ratings of the decision maker.

their co-worker's opinion) was the fair way to split the money, on an 11-point scale from "not at all certain" to "very certain" (57 out of 61 had originally indicated that an equal split was fair). Another additional measure was assessed just after the second session. Subjects were told that there was not enough time to complete the third session, so the experiment would have to be terminated. This problem had supposedly come up before, however, and in those cases it had been decided that since the decision maker was not selecting any words for the last session, there was no reason why the decision maker should distribute the money for that session. Thus subjects were told that one of the workers would decide how to divide the money for that session, and a drawing took place to decide which worker would make the decision, arranged so that the subject always won. The subject was then asked to make the allocation, and the amount given to the decision maker was used as a behavioral measure of her satisfaction with the decision maker.

Results and Discussion

The results were initially analyzed by a 2 × 2 MANOVA. This MANOVA indicated that both main effects and the interaction were significant, $F(6, 51) = 2.46$, $p < .05$, for the procedure main effect; $F(6, 51) = 4.35$, $p < .005$, for the feedback main effect; and $F(6, 51) = 2.61$, $p < .05$, for the Feedback × Procedure interaction. Univariate ANOVAs were then examined to determine the nature of these effects.

The Feedback × Procedure interaction was either significant or marginally significant on the fairness of the decision-making process ($p < .05$), the amount of money given to the decision maker ($p < .06$), and the subjects' certainty about their original opinion of the fairness of an equal division ($p < .05$). The cell means (see Table 2) and appropriate contrasts show that voice led to more positive feelings (in the form of more bonus money given to the allocator, greater perceptions of fairness, and less certainty that an equal split was fair) when the feedback from the other worker indicated that the decision was not inequitable (inequity-disconfirmed conditions, $ps < .05$), but that mute–voice differences tended to be slightly (although nonsignificantly) in the opposite direction in the inequity-confirmed conditions.

The feedback main effect was also significant on each of these measures, as well as on the subjects' ratings of the decision maker and the fairness of the decision ($ps < .05$). The cell means show that subjects were generally more content with their low outcome when co-worker's feedback indicated that there was no inequity than when it confirmed that the inequity existed. It is important to note that this difference was substantial only in the voice conditions, however, and was usually very small (or even slightly in the opposite direction) in the mute conditions.

Finally, the procedure main effect was significant only on the certainty measure ($p < .005$). Voice subjects were significantly less certain that an even split was fair, but consistent with the interaction, this was significant only in the inequity-disconfirmed condition ($p < .05$).

The obtained main effect for feedback is not surprising, given the evidence that a person's discontent with a leader will be affected by whether a fellow member of the group endorses or expresses displeasure with the leader

(Michener & Tausig, 1971; Michener & Lyons, 1972). What is striking, however, is the nature of the Feedback × Procedure interaction: Contrary to the trend within the inequity-confirmation conditions, inequity-disconfirmation subjects displayed more discontent under mute than under voice procedures. The latter result is noteworthy since it means voice has a mitigating effect on discontent over and above that due to a disconfirmation of one's own opinion. Voice–disconfirmation subjects were not only *less* distressed than mute–disconfirmation subjects about their inequitable treatment but also seemed even somewhat pleased in an absolute sense. Voice–disconfirmation subjects' ratings of the fairness of the process averaged nearly 9 on an 11-point scale, their average allocation to the decision maker was more than $1 of the available $3, and the certainty measure showed that voice–disconfirmation subjects even came to entertain some doubts about their initial judgment of what was fair.

General Discussion

The results from both of these experiments display a similar pattern, in which the voice procedure is associated with more positive affect than the mute procedure is under some circumstances (no-feedback conditions, Experiment 1; inequity-disconfirmation conditions, Experiment 2), whereas this tendency is virtually neutralized (Experiment 1) or even slightly reversed (Experiment 2) under other circumstances (inequity-confirmation conditions). This pattern is contrary to the commonsense prediction that a voice procedure should always produce less discontent than a mute procedure would because it is fairer, but the results are consistent with our contention that the positive impact of voice tends to be neutralized when the viewpoint expressed by a fellow recipient confirms one's own opinion that the allocation was unfair. An understanding of why such a confirmation mitigates the desirability of voice can be gained by first considering why voice should be desirable.

Voice may be desirable for two reasons. First, voice may be preferable to mute procedures because the latter are based on incomplete information. A mute procedure may not take into account the claims of disputants and hence may entail an inferior, or at least suspect, decision. Second, being given a voice in the decision is considered to be a fairer procedure than being given no voice. Someone who is given voice at least has a chance to defend his/her position and present his/her side of the issue. The general preference for voice over mute procedures (Houlden, LaTour, Walker, & Thibaut, 1978; LaTour, 1978; Thibaut, Walker, LaTour, & Houlden, 1974; Walker et al., 1974) is so strong that disputants with the preponderance of evidence in their favor prefer a voice procedure over a mute procedure even though it may allow their opponents to present claims more strongly and could hence promote their opponents' position. This preference is shared by the decision makers themselves when they are given absolute authority and thus might "efficiently" resolve the dispute without having to consult the disputants.

Given the desirability of voice, it might be expected to affect positively the acceptability of a decision even when that decision provides undesirable outcomes. Our results show this to be the case under two conditions: when people do not know whether anyone else would agree that they have been cheated (Experiment 1) and when they discover that a co-worker's opinion disconfirms their belief that they have been cheated (Experiment 2). Thus, when subjects were not certain that they had been treated inequitably, the voice procedure was rated fairer than the mute procedure and there was a more favorable reaction to the decision maker and to the entire situation.

On the other hand, when people learn that someone else agrees that they have been denied their just deserts (inequity-confirmation conditions), the positive impact of voice seems to be negated; indeed, our results show that when supportive social "evidence" is available, the fairness of the allocation procedure becomes essentially irrelevant. Presumably the raison d'être of having a fair procedure is to prevent inequities by improving the quality of information on which the allo-

cation decision is based, but this possible advantage is obviously not present when it is *clear* that an injustice has been done. Thus, although the voice procedure could have potentially been fairer than the mute procedure, when the voiced opinions seem to have been completely ignored such a procedure is no longer perceived to be any better than a mute procedure. Support for this view comes from our "fair process" measure, which showed that subjects in the inequity-confirmation conditions did *not* rate the voice procedure as any fairer than the mute procedure.

Although the overall pattern of results does show that some circumstances are more likely than others to promote the fair process effect, the evidence regarding when voice procedures will lead to greater *discontent* (the frustration effect) is less conclusive. Frustration effect tendencies appeared only in Experiment 2, where they were nonsignificant. The main reason that the present frustration effect tendencies were less pronounced than those in the Thibaut et al. (1974) experiment may be that voice and inequity-confirmation were confounded in the Thibaut et al. study, whereas they were manipulated independently in the present experiment. The discontent expressed by participation (voice) subjects in the Thibaut et al. study may have been due to the fact that the voice subjects were given another opinion that confirmed their feelings that the decision was inequitable. Subjects in their no-participation (mute) conditions did not receive any such supporting opinion. Since opinions confirming the inequity can substantially increase discontent (as shown in Experiment 2 and in Michener & Lyons, 1972, and Michener & Tausig, 1971), this confirming opinion may have been responsible for the obtained frustration effect in their study.

We should also point out, however, that other studies have at times found frustration effects. For example, Austin, Williams, Worchel, Wentzel, and Siegel (Note 2) found that the provision of voice in a mock trial led to greater discontent when the verdict was highly unfavorable but led to greater satisfaction when the verdict was favorable. Furthermore, the provision of voice under circumstances in which outcomes improve after voice (although cumulative outcomes remain inequitable) has been observed to create a frustration effect in at least two instances (certain conditions of an experiment by Folger, 1977, and an earlier study by Thibaut, 1950). These results indicate that the frustration effect found by Thibaut et al. may not have been due solely to the confound between voice and inequity-confirmation. This possibility, coupled with our finding that the positive effects of voice can be neutralized under certain circumstances, indicates the need for further study of the conditions under which voice can affect one's satisfaction either positively or negatively. Field studies, where involvement level and applicability are high, would be especially helpful.

New JPSP Format Delayed Until April

Recent issues of this journal carried an announcement that the *Journal of Personality and Social Psychology* would appear in January 1980 under new policies and in a new sectioned format. However, in order to publish the backlog of manuscripts accepted under present policies, the first three issues of 1980 will continue to carry articles accepted under Clyde Hendrick's Acting Editorship.

This journal will appear in April as a sectioned journal edited by Melvin Manis, Ivan D. Steiner, and Robert Hogan, as previously announced.

Interpersonal Attraction and the Polarity of Similar Attitudes: A Test of Three Balance Models

Abbas Tashakkori
Shiraz University, Shiraz, Iran

Chester A. Insko
University of North Carolina

In a variation of Byrne's anonymous-stranger technique, a PDP-11 computer was used to provide feedback on five attitude issues for each of the cells of a design created by three levels of the *p-x* variable (−2, 0, +2) and three levels of the *o-x* variable (−2, 0, +2). Measurements of *p-o* sentiment were used to test the adequacy of three models for the quantification of balance: the equal-weights tetrahedron model, the unequal-weights tetrahedron model, and the Feather model. Correlations of obtained and predicted measures for the three models were .48, .51, and .52, respectively, with various problems noted for each model. The results further revealed a predicted shift in the polarity of similar attitudes, but a predicted difference between ambivalent and indifferent neutral attitudes was not supported.

Byrne (1969, 1971) has reported a sizable amount of evidence indicating that pre-acquaintance attraction is a linear function of the proportion of similar attitudes. Similarity is defined by Byrne as "any response on the same side of the neutral point as the subject's response, and dissimilarity as any response on the opposite side of the neutral point" (1971, p. 75). As Byrne is aware, such a definition of similarity ignores the polarity of the attitude. Thus on a +3 to −3 scale, +3,+3 agreement should produce as much attraction as +1,+1 agreement. In his own words, "In effect, each item has been treated as if it were a 2-point scale with mild, moderate, and strong feelings on a given side of an issue defined as equivalents" (1971, p. 75).

As a result of some research done by Nelson (1965), Byrne did expand his formula for predicting attraction so as to include the discrepancy between the subject's and the other's attitude (for a given side of the scale), as well as the proportion of attitudes on the same side of the scale. Nelson's research found that small discrepancy produced more attraction than did large discrepancy. According to Byrne, "If a subject is strongly committed to racial integration, for example, he not only prefers integrationists to segregationists, he prefers those strongly in favor (like himself) to those mildly in favor of integration" (1971, p. 77). This expansion of the formula, however, still did not take into account the polarity of the attitude. Byrne's formula predicts, for example, that two people mildly in favor of integration should be just as attracted as two people strongly in favor of intergration.

Consideration of the possible effect of polarity (the difference between +3,+3 agreement, and +1,+1 agreement, for example) leads fairly directly to concern with 0,0 agreement, or attraction between two people who agree in having a neutral attitude. Since Byrne uses 6-point scales (possibly to simplify his definition of similarity), the whole issue of agreement between two people with neutral attitudes does not arise. Nonetheless, agreement between two people with neutral attitudes does pose a theoretical issue of some interest.

There are two quantitative formulations of balance theory (Heider, 1946, 1958) that have been developed or extended by Wellens and Thistlethwaite (1971a) so as to imply that attraction increases with increased po-

larity of similar (or agreeing) attitudes. These are Wiest's (1965) tetrahedron model, and Feather's (1967) model. As is explained below, the Feather model, as Wellens and Thistlethwaite have extended it, only predicts a change with a shift from 0 polarity, whereas the Wiest model predicts a change with every increment or decrement in polarity.

William Wiest had the ingenious idea of conceptualizing Heider's *p-o-x* triad as a cube. One dimension of the cube consists of the minus to plus values of the *p* to *o* sentiment relation, one the minus to plus values of the *p* to *x* sentiment relation, and one the minus to plus values of the *o* to *x* sentiment relation. Four of the corners of the cube represent balanced triads (the product of the three signs is positive), and four of the corners represent imbalanced triads. Connecting the balanced corners with straight lines creates a tetrahedron (a three-sided pyramid) inside the cube. Wellens and Thistlethwaite's (1971a, 1971b) representation of Wiest's three-dimensional space and tetrahedron is presented in Figure 1. In Figure 1 the *p-o* relation is symbolized as *Z*, the *p-x* relation as *X*, and the *o-x* relation as *Y*.

Wiest assumed that all balanced triads are on the surface of or within the tetrahedron. However, the assumption regarding balanced triads within the tetrahedron was modified by two further considerations. First, since points near the center of the tetrahedron are characterized by the absence of any valence for the three relations, they could better be described as "vacuously balanced" (1965, p. 3). Agreeing with Harary's (1959) postulated "tendency toward completeness," Wiest assumes that there is a force toward making "cognitive elements relevant to one another" (1965, p. 6) that moves points away from vacuous balance to balance (or from the center to the surface of the tetrahedron). The second consideration having a bearing upon the distribution of points (or triads) within the tetrahedron is also a postulated force—Osgood and Tannenbaum's (1955) assumed tendency toward maximum polarization of sentiments or attitudes. Osgood and Tannenbaum argued that attitudes have a tendency to drift toward simpler, extreme judgments

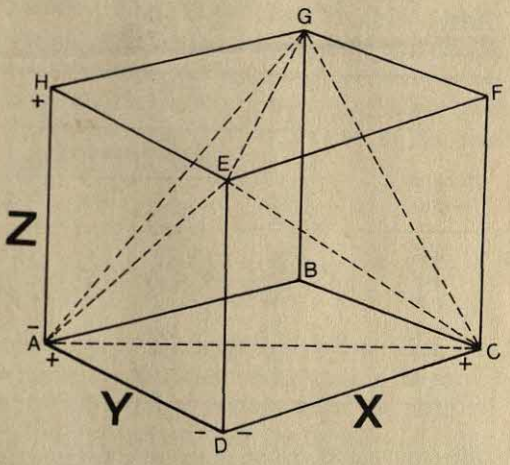

Figure 1. Wiest's three-dimensional space as defined by the three relations (or dimensions) *p-x* (*X*), *o-x* (*Y*), and *p-o* (*Z*). (From "An analysis of two quantitative theories of cognitive balance" by A. R. Wellens and D. L. Thistlethwaite, *Psychological Review*, 1971, *78*, 141–150. Copyright 1971 by the American Psychological Association. Reprinted by permission.)

and away from more difficult, discriminating judgments. Wiest agrees with this postulated tendency and assumes that it is a second force moving points toward the surface of the tetrahedron. Thus Wiest postulates that the balanced points are, by and large, on the surface of the tetrahedron.

We believe that Osgood and Tannenbaum's assumption of movement toward maximal polarity is more reasonable if the neutral attitudes, or sentiments, are characterized by ambivalence rather than indifference (cf. Kaplan, 1972). An ambivalent–neutral attitude is an imbalanced one and thus according to balance theory should be unstable. No special or additional assumption is required. In the case of indifferent attitudes, however, we are skeptical that there is any movement toward polarity. It should be further noted that if there is movement toward polarity on all three dimensions, the points should move to the corners of the tetrahedron and not just generally to the surfaces.

Wiest interpreted his tetrahedron model as having implications regarding the correlation between any two of the relations, holding the third constant at some value. The predictions were derived by "slicing" the tetrahedron at

Table 1
Predictions of the Upper- and Lower-Boundary Formulas When k = 2

p-x value	*o-x* value: Upper boundary −2	−1	0	+1	+2	*M*	Lower boundary −2	−1	0	+1	+2	*M*
+2	−2	−1	0	1	2	.0	−2	−1	0	1	2	.0
+1	−1	0	1	2	1	.6	−1	−2	−1	0	1	−.6

different points along a given relation (or dimension) and then examining the expected scatterplot for the relation between the two remaining relations. Wiest tested the tetrahedron model by calculating certain correlations among the sociometric ratings of fifth, sixth, and seventh grade children. The children initially indicated their liking for each of the other children in the class, and then indicated the extent to which the highest, intermediate, and lowest of these rated children liked, or were liked by, each of the other children in the class. Wiest confirmed the prediction that the mean correlation between *p*'s liking of *o* and *o*'s liking of *q* (or *q*'s liking of *o*) should be largest for the most liked *q* and smallest for the least liked *q*.

Wellens and Thistlethwaite (1971a) extended Wiest's model so as to enable prediction from specified values for two of the relations to some value for the third relation. If we specify two values for X and Y on the "bottom" of the cube in Figure 1 and then project this point into the cube, the projection will intersect the tetrahedron at its lower boundary and will then emerge from its upper boundary. Wellens and Thistlethwaite present the following two equations for the predicted values on the upper and lower boundaries:

$$Z_u = k - |X - Y|$$

$$Z_L = |X + Y| - k,$$

"where Z_u represents the upper boundary limit for Z; Z_L represents the lower-boundary limit for Z; $|X - Y|$ and $|X + Y|$ correspond to the absolute values of the real difference and sum, respectively, of the two given relations; and the integer k is a constant representing the highest positive scale value possible on each of the three interelement relations" (p. 142).

Illustrative predictions for the upper- and lower-boundary equations are presented in Table 1. We have specified the dependent variable as the *p* to *o* relation (Z), and have assumed a 5-point plus-to-minus scale so that $k = 2$. Since our main present concern is with the polarity of similar attitudes, the most interesting values are in the diagonal running from lower left to upper right. Note that the upper-boundary formula predicts values that are the same (+2), that is, do not differ as a function of same-sign polarity. Except for the specification of the 0,0 case, this agrees with Byrne's assumption. As Table 1 also indicates, however, the lower-boundary formula predicts a very marked effect for same-sign polarity.

Wellens and Thistlethwaite present a "generalized tetrahedron formulation" that predicts a single value for Z,

$$Z = aZ_u + bZ_L,$$

where a and b are weights for the range limits. Wellens and Thistlethwaite point out that the values for a and b will vary according to the assumptions made regarding the distribution of points between the upper and lower boundaries. Wiest assumed that the points tend to go to the surface of the tetrahedron. If it is also assumed that the points drift equally toward the two boundaries, we have a further

basis for what Wellens and Thistlethwaite refer to as an "equal-weights" tetrahedron model in which a and b are both assigned values of .5. Other distributions of points are, of course, possible, and it is worth noting that any symmetrical distribution of points could provide justification for the equal-weights model. To the extent that the distribution of points is skewed, one boundary will be weighted more heavily than the other. It does appear implicit in Wellens and Thistlethwaite's formulation that $a + b = 1$. Otherwise Z would not be an average of Z_U and Z_L.

Illustrative predictions for the equal-weights tetrahedron model are given in Table 2. Note in particular that the values along the lower left to upper right diagonal show an effect for polarity. As long as some weight is given the lower-boundary formula, the generalized tetrahedron model will predict greater attraction with greater same-sign polarity. Wellens and Thistlethwaite (1971a) found that their data were best fit by a model in which the upper boundary was weighted .75 and the lower .25. As the predicted values for this unequal-weights model show (see Table 2), there is a clear effect for same-sign polarity.

The second approach to the quantification of balance theory flows from Feather's (1967, 1971) discrepancy principle. This principle states that when two relations are of the same sign, small discrepancies will be associated with a strong positive, third relation, and when two relations are of opposite sign, large discrepancies will be associated with a strong negative, third relation. Feather (1971) wrote simple formulas for predicting the missing relation when the signs of the known relations are the same or opposite. Wellens and Thistlethwaite's (1971a) version of the two formulas is as follows:

$$Z_s = k - |X - Y|$$

$$Z_o = \frac{|X - Y|}{-2},$$

where Z_s is the missing relation when the signs of the two known relations are the same, Z_o is the missing relation when the signs of the two known relations are opposite, k is the highest possible scale value, and X and Y are the two known relations. When either X or Y is 0, Wellens and Thistlethwaite recommend averaging the values for Z_s and Z_o. Such a procedure seems more reasonable for ambivalent–neutral attitudes than for indifferent–neutral attitudes.

Illustrative predictions for the Feather model are given in Table 3. Note that the same-design diagonal values show an effect for polarity only at the 0,0 point. Since the same-sign formula is identical to the upper-boundary formula (which, however, also applies to opposite signs), it is evident that the polarity shift at the 0,0 point is due to the formula for opposite signs.

Wellens and Thistlethwaite (1971a) used a role-playing procedure to test the implications of the various models for p to o attraction. The result indicated that although all models provided a significant fit to the data,

Table 2
Predictions of the Equal-Weights and Unequal-Weights Tetrahedron Models When k = 2

M	−.2	.15	.10	.15	−.2	

an unequal-weights tetrahedron model (see Table 2) was descriptively superior to the equal-weights tetrahedron and Feather models. Wellens and Thistlethwaite (1971b) replicated this basic result but also found that for incomplete triads with *p-x* and *o-x* dependent variables "the results were best described by an equal-weights version of Wiest's tetrahedron model" (p. 82). Wellens and Thistlethwaite (1971b) speculated that perhaps the lesser importance, or lower weight, of the lower-boundary formula for predicting the *p-o* relation may be due to subjects' reluctance to imagine negative relations with others. (Note the abundance of negative relations for the lower-boundary formula in Table 1.)

The present investigation is a further study of the adequacy of the various balance models where the *p-o* relation, interpersonal attraction, is the dependent variable. The present investigation differs from the two groundbreaking experiments by Wellens and Thistlethwaite in three salient respects. First, the general experimental procedure did not involve hypothetical role playing but a variation of Byrne's anonymous-stranger technique. Second, instructions regarding the extreme values at the endpoints were used in an attempt to improve the measurement. Third, Kaplan's (1972) technique was used to measure and distinguish ambivalent and indifferent, neutral attitudes. Each of these matters will be considered in turn.

The first procedural change was to use a variation of Byrne's anonymous-stranger technique. Each subject received information regarding an anonymous stranger's attitude on five different issues. For four of the five issues the subject's attitude was −2, 0, or +2, and for four of the five issues the other's attitude was −2, 0, or +2. The exact patterns used are shown in Table 4. For example, in the +2,0 cell there are three instances in which the subject's attitude is +2 and the other's attitude is 0, one instance in which the subject's attitude is +1 and the other's attitude is 0, and one instance in which the subject's attitude is +2 and the other's attitude is (randomly) either +1 or −1. Such patterns were used in preference to completely uniform pairings in an attempt to create verisimilitude and to prevent a problem noticed during pilot testing. During pilot testing some of the subjects in cells with identical subject and other attitudes told us that they felt as if they were judging themselves. The slight variation eliminated the problem (and also reassured us that small scale differences are meaningful). The use of such a five-item procedure required that we initially pilot test so as to obtain a sufficient number of items (or item responses) to enable any subject to be randomly placed in any cell. The procedure also required that a computer be used to select the appropriate items regarding which feedback is to be given.

Table 5
Mean Predicted Attraction in Each Cell of the Design Based on the Equal-Weights Tetrahedron, the Unequal-Weights Tetrahedron, and the Feather Models

p-x value	Equal weights *o-x*				Unequal weights *o-x*				Feather (1967) *o-x*			
	−2	0	+2	*M*	−2	0	+2	*M*	−2	0	+2	*M*
+2	−1.61	−.01	1.60	−.01	−1.61	.09	1.60	.04	−1.81	−.36	1.60	−.23
0	−.01	.00	.01	.00	.09	.80	.11	.45	−.35	.70	−.34	.18
−2	1.61	.02	−1.64	.00	1.61	.13	−1.64	.06	1.61	−.32	−1.82	−.21
M	.00	.00	.00	—	.05	.45	.05	—	−.23	.18	−.22	—

Note. The slight variations from symmetry in these values are due to minor variations in the number of items per subject and to random variation in the feedback patterns (see Table 4). Note also that the marginals reflect the greater number of subjects in the 0 conditions.

From a theoretical perspective the problem is that the Wiest and Feather models apply most directly to one and not five issues. We decided to calculate the Wiest and Feather predictions for each item and then average across the five items (weight each of the items by $1/n$). Mean predicted results for the equal-weights tetrahedron model, the unequal-weights tetrahedron model, and Feather's model are presented in Table 5. All three models predict an interaction, but only the equal-weights model does not predict *p-x* and *o-x* main effects.

The second procedural change involved an attempt to improve the measurement. Anderson (e.g., 1974) has repeatedly emphasized the advantage of end-anchors for rating scales. Anderson maintains that rating scales are biased near their endpoints and that the precaution of using end-anchors overcomes possible ceiling effects that may result from such bias. According to Anderson, end-anchors are "stimuli that are higher or lower in value than the regular experimental stimuli" (1974, p. 245). We did not use end-anchors in this sense of the term, but we did attempt to incorporate the spirit of the recommendation. Thus subjects were initially instructed that the −3,+3 extremes of the scale were only for extraordinarily positive or negative feelings and that such feelings were not common. For the case of the initial instructional example, "North Carolina," they were told that the endpoints should not be used unless "you feel that there definitely isn't any place in the whole world better than it or worse than it." A reminder that the endpoints were only for extreme feelings was periodically repeated on each subject's viewing screen. With this procedure the percentage of endpoint endorsement for all items was 5.86.

Although the initial instructions and periodic reminders may provide for a more uniform interpretation of the scales, the general "anchoring" procedure does create some uncertainty regarding the k term in the various models. With a 7-point scale, $k = 3$, whereas with a 5-point scale, $k = 2$. There are a number of considerations, however, that lead us to believe that the most reasonable interpretation is for k to equal 2. Twenty-five percent of the subjects did not endorse a single endpoint on any of the scales. For these subjects, then, none of the items evoked feelings as extreme as the abstract anchor, and the effective scale was a 5-point scale. On the other hand, 75% of the subjects did endorse an endpoint for at least one item. Although there was some scatter in the items producing endpoint endorsement, the tendency was more apparent for some items than for others. Six of the 50 items had endpoint endorsements above 10%. For example, "homosexuality" produced 19% endorsement at −3, and "one true religion" produced 9% endorsement at +3 and 10% endorsement at −3. Since the computer only selected items that a given subject had endorsed at −2, 0, or +2, it is arguable that the 75% of the subjects who endorsed one or more endpoints really discovered their own idiosyncratic anchors, and thus for purposes of the items utilized in the

manipulations there was a functional 5-point scale. To the extent that the 75% of the subjects who did endorse one or more endpoints and the 25% of the subjects who did not endorse any endpoints at all had functional 5-point scales, no subjects should have endorsed an endpoint of any of the three dependent variables. In fact only 1 of the 224 subjects did so.

Beyond this it is important to note that whether k is 2 or 3 has less effect on the predicted values than might be initially thought. There is no effect at all for the equal-weights model, since the k terms exactly cancel out. For the unequal-weights model, the predicted values in each cell are all altered by the same constant, so that the magnitudes of the predicted main effects and interactions are exactly the same. For the Feather model the variation in k affects only the cells involving same signs or 0, with the result that the predicted main effects do not vary in magnitude, but the predicted interaction is somewhat smaller when $k = 2$. As far as the predicted effects for the analysis of variance are concerned, then, the exact value for k makes little or no difference. With regard to the correlation between obtained and predicted effects, the value for k makes no difference at all (since k determines intercept but not slope). Finally, with regard to the mean squared deviations of obtained and predicted effects, the value for k makes a difference only for the unequal-weights and Feather models. Accordingly, these values have been computed for both $k = 2$ and $k = 3$.

The third and final salient differences from the Wellens and Thistlethwaite studies relates to the attempt to distinguish between indifferent and ambivalent neutral attitudes. Since so much of the difference between the present study and the typical study done by Byrne relates to the inclusion of neutral attitudes, we felt it incumbent upon us to be as analytic as possible regarding such attitudes —even though neither the Wiest nor the Feather version of balance theory has been elaborated so as to take note of the distinction. Kaplan (1972) has developed a very interesting technique for measuring ambivalence. After rating an issue or concept on 7-point, bipolar, semantic-differential scal subjects use a 4-point, unipolar scale (0 to 3 to rate a concept's good qualities ignoring i negative ones, and then a 4-point, unipol scale (0 to −3) to rate a concept's bad qua ities ignoring its positive ones. Reassuringl Kaplan found that the bipolar ratings (A were highly correlated with the simple sum the unipolar positive (A_p) and the unipol negative (A_n) ratings. More relevant for pre ent purposes, however, Kaplan used the ra ings to develop a mathematical index of am bivalence (AMB). According to Kaplan,

$$AMB = TA - POL$$

(ambivalence equals total affect, TA, minu polarity, POL), where

$$TA = A_p + |A_n|$$

and

$$POL = |A_p + A_n| \simeq |A|.^1$$

It is assumed that a neutral attitude with lo ambivalence has high indifference.

For the present study half of the neutra p-x attitudes were high ambivalence and hal low ambivalence (or high indifference). Sinc an initial pilot test seemed to indicate tha the distinction had little effect, we decided t incorporate an analogous distinction into th o-x relation. Perhaps, for example, ambiv alent subjects are more attracted to ambiv alent others than to indifferent others. Sinc we were somewhat skeptical that all subject could adequately cope with feedback for thre different scales for each of the five issues, w adopted a somewhat simpler procedure. Sub jects were told that the other subject whos attitudes they were seeing had not been aske to mark the unipolar scales, as they had done but simply to check whether they were "con flicted" or "not conflicted." The meaning o the term "conflicted" was carefully describe so as to involve the inclusion of both positiv and negative qualities. Accordingly, half o the subjects receiving neutral feedback ha

[1] Kaplan (p. 369) uses $|A|$ and $|A_p + A_n|$ inter changeably in discussion of polarity. In the present study the second term was used in the calculation of ambivalence ($POL = |A_p + A_n|$).

the "conflicted" alternative checked for all five issues and half had the "not conflicted" alternative checked for all five issues. The subjects receiving either −2 or +2 feedback had the "not conflicted" alternative checked. It is mathematically impossible for subjects with highly polarized attitudes to be conflicted or ambivalent.

Since we were initially uncertain regarding how to include the above ambivalence–indifference distinction in the model testing, we decided to do a two-step analysis in which the first analysis related solely to the p-x neutral cells. If the ambivalence–indifference distinction made no difference, the cells would be collapsed. If the distinction did make a difference, the two types of neutral attitudes would be separately included with the remaining cells of the design.

Method

Subjects

The subjects were 224 students (80 male and 144 female) from the introductory psychology class at the University of North Carolina who participated in partial fulfillment of a course requirement.

Independent Variables

The design can be conceived of as involving two, four-level factors (p-x by o-x). The four levels of the p-x factor are −2, 0 indifference, 0 ambivalence, and +2. The four levels of the o-x variable are −2 nonconflicted, 0 nonconflicted, 0 conflicted, and +2 nonconflicted.

The p-x factor was manipulated by having the PDP-11 search for five items that conformed to the subject's randomly assigned condition. If the subject were assigned to a 0 attitude condition, the computer calculated the ambivalence scores for all these items, ranked the scores, and then selected either the four highest or the four lowest. A similar procedure was used for the fifth, +1 or −1, item. Mean ambivalence for all five items was .19 for 0 indifference and 1.63 for 0 ambivalence.[2] Whether the fifth item was +1 or −1 was randomly determined.

Although the initial set of 50 items had been selected so as to maximize the probability of always finding five appropriate items for any randomly assigned condition, in 17 of the 224 cases we were forced to use fewer than five items. In 11 cases four items were used, and in 6 cases three items were used. Since omitting these subjects from the various multivariate and univariate tests made no difference in the results, all subsequently reported analyses include these 17 subjects.

The o-x factor was manipulated by having the computer provide feedback regarding the other's attitude according to the pattern in Table 4. Information was also provided regarding whether the subject was conflicted. Except for the 0 conflicted case, the nonconflicted alternative was always indicated.

Procedure

The experiment was conducted on a PDP-11 computer. Subjects were tested in separate, soundproof cubicles. The instructions and other information were presented to each subject on a cathode ray tube screen, and subjects responded by using different keys on a teletypewriter.

Upon arrival subjects were informed, consistent with information provided on the "sign-up" sheet, that they were going to participate in two different experiments, one concerned with attitude measurement and one concerned with impression formation on the basis of limited information. Subjects were then directed to separate cubicles and were instructed regarding the use of the teletype. Each subject was randomly assigned to a cell of the design, and the cell number was fed into the computer.

In the first experiment subjects were presented with 50 attitude items relating to a miscellaneous set of issues (supersonic planes, gun-control laws, the honor system, communes, nuclear energy, divorce, etc.). Subjects initially responded to the items on a 7-point, bipolar scale, then on a 4-point, positive, unipolar scale, and finally on a 4-point, negative, unipolar scale. The bipolar scale was labeled: extremely in favor, 1 = (+3); strongly in favor, 2 = (2); mildly in favor, 3 = (+1); undecided or neutral, 4 = (0); mildly against, 5 = (−1); strongly against, 6 = (−2); extremely against, 7 = (−3). Instructions for the bipolar scale used the example of "North Carolina":

> You should type the number of any of these options which best represents your feelings about North Carolina. For example, if you feel very positively about North Carolina you should type 2 (strongly in favor). The two endpoints 1 (+3) and 7 (−3) are indicators of very extreme feelings which are not common in the majority of cases. You may use them only if you have an extraordinarily positive or negative feeling about an issue (e.g., in the case of North Carolina, if you feel that there definitely isn't any place in the whole world better than it or worse than it!).

The above instructions, along with additional information indicating that the 0 point could indicate either conflicting feelings or indifference, were followed by a practice example. The first 4 items and

---

[2] If $POL = |A|$, mean ambivalence is .67 for indifference, and 1.88 for ambivalence.

then every 10th item were preceded by the following reminder:

> Please indicate your feelings about the following statement by typing the number of your selected option. Remember that options 1 (+3) and 7 (−3) are for very, very extreme feelings that are not common in many cases.

Consistent with Kaplan's (1972) suggestion, the positive, unipolar rating was introduced with instructions to rate the positive qualities, ignoring the negative. The example was "ice cream" (taste vs. calories).

Following the negative, unipolar rating, the second experiment was introduced. Subjects were asked to press a button if they wished to participate in the second experiment. The instructions were in the vein of the typical "judgment about others on the basis of limited information," except for the inclusion of detailed information regarding the other's indication of whether he or she was "conflicted" or "not conflicted." The other was described as some other University of North Carolina undergraduate of the same sex as the subject. At the time this person rated the items, the unipolar scales had not been used; rather a simple decision regarding the conflicted–nonconflicted dichotomy was made. Again an example was given. The feedback regarding the other's bipolar responses followed the pattern in Table 4. The information regarding the other's response to each item was shown on the screen for 20 sec, and at the same time a copy was printed on the teletype for later reference.

After the fifth item was presented, the subjects were given the several items of Byrne's Interpersonal Judgment Scale (IJS). Subjects were again reminded that the endpoints were for extreme feelings.

Finally, subjects were taken to a different room and were asked to fill out a brief questionnaire that asked for further ratings of the other, as well as information regarding their general impressions of the other and also opinions they had regarding the purpose of the experiment.

Dependent Variables

The main dependent variable is the 7-point rating of liking from the IJS. The IJS also includes an item regarding liking to work with the other person in an experiment. The final questionnaire contained one final item of related interest. This was a 7-point rating of the extent to which the other "would like you if you were to meet." As Heider stated balance theory, there was an expectation that liking and perceived reciprocal liking would be correlated. We regard the liking measure as the most direct measure of attraction. Preference as a work partner (working) and reciprocal liking are less direct measures of attraction.

Results

MANOVA

A two-factor (4 × 4) multivariate analysis of variance (MANOVA) of the three main dependent variables (liking, working, and reciprocal liking) revealed a significant interaction, $F(26, 602) = 4.41$, $p < .01$, and no main effects for p-x, $F(9, 501) = 1.62$, $p < .11$, or o-x, $F(9, 501) = 0.01$, $p < .51$. These results are in agreement with the predictions of the equal-weights tetrahedron model and in partial disagreement with the unequal-weights and Feather models (since they also predicted main effects). Since, as is explained below, the different types of neutral attitude produced no significant variation, we will initially examine these dependent variables with the different types of neutral attitude collapsed. Such a procedure facilitates testing of the various models.

Liking

A 3 × 3 analysis of variance (ANOVA) of the liking scores revealed a significant interaction, $F(4, 215) = 20.29$, $p < .01$, and nonsignificant main effects for p-x, $F(2, 215) = 1.36$, and o-x, $F(2, 215) = .59$. A trend analysis of the interaction revealed both a significant linear by linear component, $F(1, 215) = 69.08$, $p < .01$, and a significant quadratic by quadratic component, $F(1, 215) = 11.40$, $p < .01$. The liking means are in Table 6. As the interaction indicates, there is a tendency for the means to increase across the top row and to decrease across the bottom row. A trend analysis of just the top, +2, row reveals a significant linear trend, $F(1, 215) = 28.37$, $p < .01$, and a nonsignificant quadratic trend, $F(1, 215) = .83$. Across the middle, 0, row the linear trend is nonsignificant, $F(1, 215) = .42$, but the quadratic trend is significant, $F(1, 215) = 7.09$, $p < .01$. Across the bottom, −2, row the linear trend is significant, $F(1, 215) = 41.32$, $p < .01$, as is also the quadratic trend, $F(1, 215) = 4.32$, $p < .01$. Finally, in view of our particular interest in polarity it is relevant to note that similar extreme attitudes (+2,+2 or −2,−2) pro-

Table 6
Mean Liking, Preference As a Co-worker, and Reciprocal Liking

p-x value	Liking *o-x*				Working *o-x*				Reciprocation *o-x*

+2	−.64	.14	1.43	.27	−.50	−.14	1.14	.09	−.43	.50	1.36	.48
0	.21	.64	.04	.38	.21	.34	.18	.27	.36	.89	.39	.63
−2	1.64	−.18	−.86	.11	1.07	−.14	−.64	.04	1.43	.29	−.21	.45
M	.36	.31	.16	—	.25	.10	.21		.43	.64	.48	

Note. The marginals reflect the greater number of subjects in the 0 conditions.

duced more attraction than similar neutral attitudes, $F(1, 215) = 13.94$, $p < .01$.

All of the theoretical models predict interactions, but only the equal-weights model does not predict main effects. Since no main effects were obtained, this result provides support for the equal-weights model. On the other hand, the nature of the obtained interaction is only partially in accord with the equal-weights model. As the theoretical values in Table 5 indicate, the equal-weights model predicts a linear by linear interaction with an increasing linear trend across the +2 row, no trend across the 0 row, and a decreasing linear trend across the −2 row. These predicted linear effects are significant. There are also significant quadratic effects, however. Particularly noteworthy is the quadratic trend across the 0 row produced by the rise in the 0,0 cell. This quadratic or curvilinear trend is interesting because such an effect is predicted by both the unequal-weights and Feather models (see Table 5).

Finally, there is also a significant quadratic trend across the −2 row. This curvilinear trend appears to result from the fact that the −2,−2 mean (1.64) is not as discrepant from the 0,0 mean (−.18) as is the −2,+2 mean (−.86). Stated somewhat differently, the same-sign mean is more polarized in the positive direction than the opposite-sign mean is in the negative direction. Although the curvilinear trend is not significant across the top, +2, row, there is a similar tendency for the same-sign (+2,+2) mean (1.43) to be more polarized in the positive direction than the opposite-sign (−2,+2) mean (−.64) is in the negative direction. An overall test of the difference between the absolute values of these same-sign and opposite-sign means (for the corner cells) is significant, $F(1, 215) = 8.60$, $p < .01$.

Table 7 presents the correlations and mean squared deviations between obtained and predicted values for the various Wiest and Feather formulations. For sake of comparability with Wellens and Thistlethwaite analyses, the calculations have been done separately for upper- and lower-boundary formulas and also for three different formulations of the Feather model. The composite model uses the average of the same- and opposite-sign formulas when *p-o* or *o-x* is neutral. The same-sign predictions are based on the same-sign formula for neutral attitudes, and the opposite-sign predictions are based on the opposite-sign formula for neutral attitudes. In all other respects the three Feather formulations are identical. The two Wiest models differ according to whether the weights are equal ($a = .5$, $b = .5$) or unequal ($a = .75$, $b = .25$). In terms of mean squared deviations from pre-

Table 7
Correlations Between and Mean Squared Deviations of Obtained and Predicted Liking Values

Basis of prediction	*MSD* ($k=2$)	*MSD* ($k=3$)	*r*
Upper-boundary formula	1.36	2.79	.48*
Lower-boundary formula	2.42	5.01	.28*
Equal-weights model	1.22	1.22	.48*
Unequal-weights model	1.13	1.34	.51*
Feather same-sign	1.41	2.93	.46*
Feather opposite-sign	1.79	1.93	.50*
Feather composite model	1.24	1.39	.52*

* $p < .01$.

dictions, the equal-weights, unequal-weights, and Feather models are descriptively smallest, and the lower-boundary formula is descriptively largest. This is true for both $k = 2$ and $k = 3$. Since no appropriate tests of significance are possible, some care should be exercised in interpreting these results.

In terms of the correlation of predicted and obtained results, the coefficients for the three models are approximately the same. In this instance it is possible to do tests of significance—assuming one is not concerned with the problem of repeated testing. As it turned out, however, that concern is not relevant, since comparisons among all possible pairs of the three models (equal weights, unequal weights, and Feather composite) produced p values greater than .05 in every case.

The data in Table 7 descriptively indicate that the lower-boundary formula has both the largest mean squared deviation and the lowest correlation. A stepwise regression analysis, however, reveals that the lower-boundary formula is necessary to the Wiest formulation. With only the best predictor (upper-boundary formula) in the model, the correlation is .48. When the lower-boundary formula is added, the (multiple) correlation increases to .51 and the difference is statistically significant, $F(1, 221) = 29.00$, $p < .01$. The multiple regression equation for $k = 2$ is as follows:

$$\text{Liking} = .14 + .49\ (\text{upper}) + .20\ (\text{lower}).$$

With $k = 3$, the intercept changes from .14 to −.15.

It is interesting to note that the above equation gives greater weight to the upper boundary than to the lower. The difference between the two weights is, in fact, significant, $F(1, 221) = 7.36$, $p < .01$. Thus the assumption of "equal weights" is not justified for the present data.

In view of the fact that the generalized tetrahedron formula assumes a 0 intercept, it is of interest to calculate the weights or slopes for the upper and lower boundary when the scores have been standardized so as to guarantee a 0 intercept. These weights, .43 (upper) and .18 (lower), are not appreciably changed from the above values of .49 and .20. When the weights are rescaled so as to sum to 1, they are approximately .70 and .30—not greatly different from Wellens and Thistlethwaite's "unequal weights" of .75 and .25.

Examination of the lower-left to upper-right diagonal values in Table 1 makes it evident that the lower-boundary formula predicts a polarity shift for same-sign values. The reason for this is that the $|X + Y|$ term of the lower-boundary formula is exactly equal to a direct measure of polarity, $|X| + |Y|$, for same-sign values. This suggests the use of a stepwise regression to demonstrate further the importance of polarity. The two terms are $|X - Y|$ from the upper-boundary formula and the direct measure of polarity, $|X| + |Y|$. The best predictor, $|X - Y|$, correlates .48 with liking, and the correlation increases to .52, significantly higher, $F(1, 222) = 38.20$, $p < .01$, when polarity is added. For same-sign values the first term, $|X - Y|$, is a measure of discrepancy. This suggests that the limited success of the tetrahedron model is at least partially due to the fact that it includes simultaneous measures of both discrepancy and polarity.

Working

Table 6 reports the mean working (preference for working within an experiment) results. An analysis of variance revealed a significant interaction, $F(4, 215) = 10.53$, $p < .01$, and no significant main effect for p-x, $F(2, 215) = 1.17$, $p < .31$, or o-x, $F(2, 215) = .50$, $p < .61$. Both the linear component of the interaction, $F(1, 215) = 37.93$, $p < .01$, and the quadratic component of the interaction, $F(1, 215) = 4.12$, $p < .05$, are significant. Trend analyses of the separate rows revealed a linear effect in the +2 rows, $F(1, 215) = 18.7$, $p < .01$, and a linear effect in the −2 row, $F(1, 215) = 19.78$, $p < .01$. No other trends, linear or quadratic, are significant. The quadratic interaction appears to result partially from the somewhat greater deviation from the 0 level of the same-sign than from the opposite-sign corner means. A comparison of the absolute value of the same-sign corner cells with the absolute values of the opposite-sign corner means is marginal, $F(1, 215) = 3.85$, $p < .06$. These results are

a somewhat weak parallel of the liking results. As was the case for liking, similar extreme attitudes (+2,+2 or −2,−2) produced more attraction than similar neutral attitudes, $F(1, 215) = 12.14$, $p < .01$.

Reciprocal Liking

Table 6 reports mean reciprocal liking (perceived reciprocal liking) results. An analysis of variance revealed a significant interaction, $F(4, 215) = 17.54$, $p < .01$, and no significant main effect for *p-x*, $F(2, 215) = 1.20$, $p < .30$, or *o-x*, $F(2, 215) = 1.49$, $p < .23$. Both the linear component of the interaction, $F(1, 215) = 59.93$, $p < .01$, and the quadratic component of the interaction $F(1, 215) = 8.90$, $p < .01$, are significant. Trend analyses of the separate rows revealed significant linear effects in the +2 row, $F(1, 215) = 32.51$, $p < .01$, and −2 row, $F(1, 215) = 27.52$, $p < .01$. There is also a significant quadratic trend in the 0 row, $F(1, 215) = 10.94$, $p < .01$. No other trends are significant. A comparison of the absolute value of the same-sign corner cell with the absolute value of the unlike corner cells is significant $F(1, 215) = 23.67$, $p < .01$. Except for the lack of a significant quadratic trend in the −2 row, these results parallel those for liking. Again, similar extreme attitudes (+2,+2 or −2,−2) produced a greater effect than similar neutral attitudes, $F(1, 215) = 40.49$, $p < .01$.

Reactions to Neutral Others

In view of the fact that one of the major purposes of the present study is to examine the effect of neutral attitudes, it is of interest to note some of the written comments regarding neutral others. The postexperimental questionnaire contained a question that asked subjects to indicate whether or not they had any specific individual in mind when responding to questions about the other person. It is interesting to note that regardless of the type of response (yes or no), some subjects elaborated by expressing negative attitudes toward the stranger when he or she had neutral attitudes. Here is a sample of some of the comments: "someone who is wishy-washy or uninformed," "a blah sort of person in that he did not feel any way about any issue," "someone indifferent to the society," "(someone with) little feelings about current issues," "(one who) didn't care about anything," "some dumb female who didn't care about anything but her own private world," "(I don't) know anybody who has no opinion," "(a person who) didn't have any opinion about anything," "a person who wouldn't make up his mind on anything,"and "someone strongly individualistic enough to not really care."

Table 8
Mean Liking of Ambivalent and Indifferent Neutral Subjects

p-x value	*o-x* value				
	-2_n	0_n	0_c	$+2_n$	*M*
0_{ind}	.86	.93	.93	−.14	.64
0_{amb}	−.43	.57	.14	.21	.12
M	.21	.75	.54	.03	—

Note. Subscript *n* symbolizes nonconflicted and subscript *c* conflicted.

Even some of the subjects who were themselves neutral expressed negative feelings about the neutral other. Here are some of their comments: "a freshman (who) didn't seem to be extremely well-informed, close to myself," "a friend of mine who is always neutral about everything," "(a person who) is not well acquainted with current events, just like me," "(a person who) was not very intelligent, someone who was indecisive on a lot of topics," "a very indecisive person," "a very unopinionated (person)," and "(a person) who does not keep up with current events." In view of the fact that these comments came in response to a very indirect question (regarding whether or not they had a specific individual in mind), their negative tone is somewhat surprising. Some subjects at least appear to have generalized beyond the small amount of conveyed information so as to regard the other as "empty headed."

Type of Neutral Attitude

Table 8 presents the mean liking results for the ambivalent and indifferent levels of

the *p-x* factor and the cross-cutting levels of the *o-x* factor (some of which are conflicted and some of which are nonconflicted). As previously indicated, a 4 × 4 multivariate analysis of variance for liking, working, and reciprocal liking revealed that neither main effect (*p-x* or *o-x*) is significant. Our planned comparisons, however, relate to the interaction within the four center cells (see Table 8). Specifically, it was predicted that attraction would be greater for the indifferent–nonconflicted and ambivalent–conflicted cells than for the ambivalent–nonconflicted and indifferent–conflicted cells. A multivariate test of this interaction is nonsignificant, as are also each of the three univariate tests. In the case of liking and working, the interaction is in fact in the "wrong" direction.

In order to be somewhat more certain about the above findings, an internal analysis was done by selecting subjects who differed more extremely on ambivalence–indifference. The results were not appreciably changed.

Within-Cell Distributions

One final matter relates to the within-cell distribution of liking scores. Wellens and Thistlethwaite (1971a, 1971b) report that their within-cell distributions were not noticeably bimodal and took this as evidence against Wiest's assumption that the points inside the tetrahedron go toward the two surfaces or boundaries. Such a test, however, rests on the assumption that individuals will markedly differ in the extent to which upper- or lower-boundary forces predominate—an assumption that may or may not be true. In any event, we also did not notice any marked tendency toward bimodality in the nine cells of the design. Most of the cells appeared unimodal with moderate skew. The third moments (measures of skewness) for each of the cells are as follows: .065, −.431, −.430, −.264, .487, .268, 1.375, −2.175, .70. Assuming that individuals markedly differ in the extent to which upper- or lower-boundary forces predominate, the equal weights model would assume symmetrical distributions.

Discussion

The obtained results leave little doubt that a same-sign shift in polarity from +2,+2 or −2,−2 to 0,0 has a marked effect on interpersonal attraction. This result was obtained for all measures, direct and indirect. Beyond this, the results give some qualified support to the equal-weights tetrahedron, unequal-weights tetrahedron, and Feather model, with no unqualified support for any one of the models. The equal-weights tetrahedron model is the only one that predicts the obtained pattern of an interaction and no main effects. According to the equal-weights tetrahedron model, however, the interaction should be entirely linear (see Table 5). In fact, both the linear and quadratic interactions are significant for all three dependent variables (liking, working, and reciprocal liking). One aspect of this quadratic interaction is a tendency for a curvilinear trend to appear in the 0 row. Such a trend (which is not predicted by the equal-weights model but is predicted by the unequal-weights and Feather models) is significant for both liking and reciprocal liking and nonsignificant but in the same direction for working (see Table 6). These ANOVA results, then, are not entirely in accord with any of the three models.

The mean squared deviations of the obtained from predicted values and the correlation between the obtained and predicted values are approximately the same for all three models (see Table 7). The three versions of the Feather formulation are fairly similar, with a slight descriptive edge going to the composite model. The most apparent thing from the Table 7 measures is the relatively lower correlation and higher mean squared deviation for the lower boundary formula. This impression is further buttressed by the finding that the multiple regression weight for the upper boundary is significantly greater than for the lower boundary. This rather clearly indicates that the data are not consistent with the equal-weights model. Overall, then, we are left with a somewhat mixed picture.

One of the most apparent problems is the failure of the subjects to report as much dis-

like as any of the models predict. Particularly noteworthy is the failure of the opposite-sign (or dissimilar) 2,2 cells to be as extreme in the negative direction as the same-sign (or similar) 2,2 cells are in the positive direction (see Table 6).[3] Judging from the numerous studies reported by Byrne, our subjects' reluctance to express extreme dislike when there is high dissimilarity is a typical occurrence. What is responsible for this phenomenon? A brief digression suggests a possible answer.

Aronson and Worchel (1966) have advanced the interesting idea that the similarity–attraction effect is due, "at least in part, to an implicit assumption that people who hold attitudes similar to our own will like us" (p. 157). By extrapolation one could also infer that there is an implicit assumption that people who hold attributes dissimilar to our own will dislike us. The reciprocal liking results for the present study (see Table 6) do indeed indicate that similarity information does have implications for perceived reciprocal liking (and disliking). Insko, Thompson, Stroebe, Shaud, Pinner, and Layton (1973) obtained similar results, and, in addition, found further support for this "implied evaluation" hypothesis with an experimental manipulation of evaluative feedback. As predicted by this hypothesis, the slope of the similarity–attraction effect was less when evaluation feedback was either positive or negative than when it was absent. Similar results were obtained by Byrne and Rhamey (1965) and also by Clore and Baldridge (1970).

There is, therefore, evidence in support of this implied-evaluation hypothesis. Since balance theory, as stated by Heider (1958), clearly asserts that reciprocal, *p-o* liking–disliking is balanced, the implied-evaluation hypothesis can be regarded as a type of balance explanation of the similarity–attraction effect. It is an explanation that focuses attention on balance in the *p-o*, *o-p* cycle, as opposed to the emphasis upon balance in the *p-o-x* cycle. There is nothing in balance theory that states before the fact which cycle or cycles will be important. Rather, balance theory simply points to the importance of any implicit aspects of *p*'s phenomenology and assumes that the basic tendency to maintain or achieve balance always operates. It can be further noted that balance theory allows for the possibility of any of a number of causal sequences among the three variables of similarity, *p-o* sentiment, and *o-p* sentiment. Aronson and Worchel's hypothesis suggests that similarity affects *p-o* sentiment directly and also indirectly via the mediation of *o-p* sentiment. Other possibilities exist, however; for example, that similarity causes *p-o* sentiment, which causes *o-p* sentiment, which feeds back to *p-o* sentiment (cf. Insko et al., 1973).

For present purposes, however, it is interesting to note that the (direct or indirect) inference from similarity to reciprocal liking is stronger than is the inference from dissimilarity to reciprocal disliking. As the data in Table 6 indicate (and consistent with the less marked but still evident results for liking), the opposite-sign 2,2 cells are not as extreme in the negative direction as the same-sign 2,2 cells are in the positive direction. Why should this be? There is nothing in the *p-o*, *o-p* cycle per se that would predict such a result. It is, however, evident that for the typical person of high self-esteem the simultaneous occurrence of *p-o* liking and *o-p* liking produces agreement regarding the worth of the self, but the simultaneous occurrence of *p-o* disliking and *o-p* disliking produces disagreement regarding the worth of the self. Common sense certainly suggests that there is some tendency to avoid disagreement regarding the worth of the self. What is the reason for such avoidance? Social comparison theory (Festinger, 1954), of course, predicts a general avoidance of all disagreement—assuming that the *o*s are similar. On the other hand, balance theory more simply predicts the same effect. Assuming a positively evaluated self, and that disagreement implies negative evaluation, it is imbalanced for the self (+) to be

---

[3] It is interesting to note that with $k = 3$, the unequal-weights and Feather models actually predict that the opposite-sign, corner means should not be as negative as the same-sign, corner means are positive. The obtained data, however, show this tendency much more markedly than is predicted under this circumstance.

(+) negatively evaluated (−). In this instance the verb "to be" implies equality, or similar grouping, and is thus a positive unit relation. Whatever the theoretical basis for this avoidance of disagreement phenomenon, its assumed reality provides a possible explanation for the failure of the opposite-sign, high-dissimilarity cells to produce the predicted amount of disliking. The inference from dissimilarity to *p-o* disliking would be weakened because of the suggestion of *o-p* disliking, which (for the typical high self-esteem person implies disagreement regarding the worth of the self. Such a complex feedback system could account for the lesser polarity of the opposite-sign, corner cells. Incorporation of such speculation into a model that includes some version of the Wiest or Feather formulations represents a major theoretical challenge.

Aside from such complexities, close examination of the Feather model makes apparent that it predicts some fairly implausible results in the neighborhood of 0,0. Thus with X and Y both equal to .001, the predicted $Z = 2$; however, with opposite signs so that $X = -.001$ and $Y = .001$, the predicted $Z = .001$. The problem arises from the fact that the same- and opposite-sign formulas predict such differing results, and as both X and Y approach 0, such large differences do not appear reasonable.[4]

Finally, it is clear that the experiment did not support our initial expectations regarding the difference between ambivalent– and indifferent–neutral attitudes. We think that Kaplan's technique is an interesting one, and that the distraction between the two types of attitudes may indeed be important in some research contexts—for example, the problem of stability or instability of an attitude structure. Our data, however, do not indicate that the distinction is important in the context of interpersonal attraction. In the course of our research, one problem with Kaplan's scheme did become evident. Kaplan does not distinguish between indifferent–don't-care attitudes and indifferent–don't-know attitudes. Possibly this was less of a problem in the recent past than in these times of increasingly "unprepared" students.[5] In general, however, this issue needs to be addressed. It may be that the more that is known about an object, the less likely it is that the attitude toward the object will be indifferent.

[4] We are indebted to the action editor for pointing this out to us.

[5] We were amazed to learn that some subjects felt that "socialized medicine" had to do with the kind of training that MDs receive.

Personality Structure and the Circumplex

Douglas N. Jackson
University of Western Ontario

Edward Helmes
London Psychiatric Hospital
London, Canada

A computer simulation employing the responses of hypothetical respondents answering solely in terms of Jackson's threshold model for stylistic responding reproduced closely the circumplex structure reported by Wiggins as representing adjective trait endorsements in the interpersonal domain of personality. Wiggins' data are interpreted as defining two general dimensions, the first representing the differential salience of trait desirability, and the second, differential thresholds for responding desirably in the middle range, resulting in the endorsement of many or few traits as self-descriptive. These processes are considered of fundamental importance in self-description and presentation but are stylistic in nature and are to be distinguished from trait content. The circumplex structuring of trait content is considered too simple a model for describing the complexities of personality and is judged to be inconsistent with much of modern measurement theory, which highlights convergent and discriminant validity, simple structure, and the mutual independence of traits.

There is much that is commendable in Wiggins' (1979) approach to the classification of personality. It is *systematic* in that it seeks to distinguish definitionally a number of domains of enduring personality dispositions or traits; it is *scholarly* in that it seeks to incorporate a number of previous conceptualizations; it is *integrative* in that it seeks to relate, relatively exhaustively, diverse traits; and it is *empirically based* because certain data are presented that purport to support a particular interpretation of trait structure. We do not take issue with the value to personality theory of systematic taxonomic efforts. In this paper we take issue primarily with Wiggins' interpretation of his empirical data and its supposed relevance to the structuring of personality trait content in the interpersonal domain.

This work was supported by Research Grant 410-77-0320-R1 from the Social Sciences and Humanities Research Council of Canada and was completed while Douglas N. Jackson was at the Pennsylvania State University on a Social Sciences and Humanities Research Council of Canada Leave Fellowship. The authors thank Jerry S. Wiggins for uncovering an error in a previous draft.

Wiggins distinguished interpersonal traits from those derived from other domains, such as those based on "temperament," "character," and "qualities of mind as manifested in thought, perception, and speech." Within the domain of interpersonal traits, he has identified eight theoretical variables, labeled (with accompanying abbreviations): Gregarious-Extraverted (NO), Ambitious-Dominant (PA), Arrogant-Calculating (BC), Cold-Quarrelsome (DE), Aloof-Introverted (FG), Lazy-Submissive (HI), Unassuming-Ingenuous (JK), and Warm-Agreeable (LM). He hypothesizes that measures of adjacent variable should be correlated, and if arrayed in a circle, correlations should decrease between variables as a function of their mutual distance along the circumference of the circle. Wiggins proceeded to identify 16 specific trait dimensions, and on the basis of rational criteria as well as empirical item response statistics and desirability ratings, he selected eight adjectives to define each trait. Similar pairs of traits were combined into broader categories yielding eight measures corresponding to the eight theoretical traits. These were intercorrelated and factored by principal components. A plotting of the two largest dimensions yielded the circular array of traits, ap-

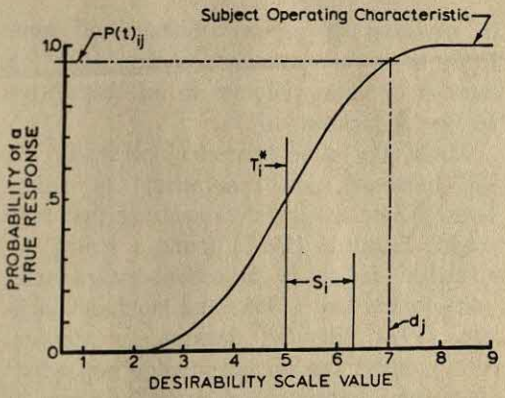
parently confirming the hypothesized structure. Wiggins seems to attach psychological importance to this structure, corresponding to what Guttman (1954) termed a circumplex.

We shall present evidence that Wiggins' findings regarding personality trait structure are subject to a very plausible alternative interpretation. We shall also suggest that his approach to the measurement of personality is not consistent with modern measurement theory and shall argue that as a model for describing behavioral consistency, a circumplex structuring of personality traits is an incomplete oversimplification. The latter is not to say that important processes may not underlie the reported circumplex structure. We shall argue that although they are not uniquely relevant to particular traits, these processes are of fundamental importance in personality assessment and interpersonal behavior.

An Interpretation of Processes Underlying the Circumplex

There is now considerable evidence that responses to personality questionnaires and judgments of the personality of others are related to the desirability level of the items being judged or endorsed. The probability of a true response to a personality statement or adjective by a group of respondents, for example, has been found to be a function of the judged desirability of the item. This finding has been observed over a wide variety of personality item content and respondent populations. Of course, this functional relationship, as Norman (1967) has noted, applies to item statistics and scale values, not to individual differences. But it is possible to compute individual probabilities of responding to items at similar levels of desirability by grouping items with similar scale values. When this is done, individuals show diverse patterns of responding (Jackson & Messick, 1969). Some respond in a manner highly related to desirability scale values; some respond as if they were unaware of desirability. For the former one might say that desirability is *salient*; for the latter it apparently is not. Furthermore, when



Derivation of the Probability of a True Response on Item j, for Subject i with the following Parameters:

T_i^* = Desirability Responding Threshold = 5
S_i = Salience Parameter = 1.25
d_j = Desirability of Item = 7
$P(t)_{ij}$ = Probability of a True Response = .94

Figure 1. Description of the threshold model.

one plots the functional relation between an individual's frequency of a true response to items having different levels of desirability scale values, one finds that some persons tend to endorse many characteristics as self-descriptive in the middle range of desirability, whereas others do so only at relatively higher levels of desirability. This implies different *thresholds* for responding desirably.

These two parameters, the individual salience of the desirability dimension (or the respondent's *sensitivity* to desirability) and the threshold for responding desirably in interaction with a stimulus parameter, the judged desirability scale value of a personality item, were the central features of the threshold formulation for stylistic responding, proposed a decade ago (cf. Voyce & Jackson, 1977; Jackson, Note 1). This model is represented in Figure 1. Using this formulation, in which salience corresponds to the *slope* of the individual function relating probability of responding true and the threshold corresponds to some median probability of a true response, processes underlying previous findings (Edwards, 1963; Jackson & Messick, 1961, 1962a) have been clarified. Measures of salience and threshold, for example, have been found to show highest loadings in the two-dimensional circumplex structure found

in measures of psychopathology and were found to be very strongly associated with the number of items endorsed as self-descriptive (Voyce & Jackson, 1977).

Might the same processes operate in the self-characterization endorsement of adjectives? There is suggestive evidence that they might. Edwards (1957) found a strong desirability factor in adjective endorsement. Jackson and Lay (1968) and Morf and Jackson (1972; Bentler, Jackson, & Messick, 1971) report two factors in endorsing adjectives, one associated with the tendency to endorse desirable adjectives (related to responding desirably to personality items) and the other associated with endorsing many adjectives (linked in a second-order factor to the tendency to endorse many personality items as self-descriptive). A similar circumplex patterning of correlations and factor loadings was reported for three factor analyses of the Minnesota Multiphasic Personality Inventory (MMPI; Jackson & Messick, 1961, 1962a, b). The question arises, what would happen if a group of respondents answered the Wiggins adjectives in terms of the threshold model, holding constant all other phenomena? Would they yield a circumplex similar to that of Wiggins? With human respondents one has no way of knowing with certainty that they would follow instructions to answer in terms of the threshold model, even if it could be communicated to them, and to ignore other influences, such as item content. But it is a relatively simple matter to program a computer to simulate the responses of a number of hypothetical subjects instructed to answer solely in terms of the threshold model (Rogers, 1971).

Computer Simulation of Adjective Endorsements

A computer program was written to simulate the responses of 500 subjects. The primary source of scale values for social desirability for the adjectives was Norman (Note 2). Three adjectives (dominant, appreciative, and enthusiastic) were not in the Norman list, and scale values were obtained from the Goldberg data (Note 3). A scale value for one adjective (organized) could not be located and was given a neutral scale value of 5.0. All scale values are based on the mean of the mean ratings of the two sexes reported by Norman (Note 2) and Goldberg (Note 3).

The simulation program predicted responses to the 128 adjectives for each of the 500 subjects on a 9-point Likert scale. The program first generated two independent, random numbers from a standard normal distribution. One number was rescaled, using a predetermined value for mean and standard deviation, to the salience parameter. Corresponding values were used to rescale the second number as a threshold. The value of threshold was then converted to the equivalent value of the intercept of the straight line illustrated in Figure 1, using a value of 5 for the value of the ordinate in the equation of the line.

To predict item responses, the values of the threshold (intercept) and the salience (slope) were used in the linear prediction equation with the social desirability scale values for the adjectives. The predicted response was rounded to the nearest integer value (1 to 9), which was then taken as the value of the response to that adjective. Responses were then summed to form scores for the eight scales.

The threshold model describes the process by which a person ascribes traits as self descriptive at different levels of desirability. This adds a slight complication in the case of negations. Consider the trait *uncrafty*. A "false" (or "uncharacteristic") response to *uncrafty* implies the presence of the trait *crafty*. Thus in the case of items containing a negation, it is necessary to consider the desirability scale value of the unnegated adjective. The Wiggins scale contains 46 such negations in four octant scales. The social desirability scale values for unnegated forms of these adjectives (obtained from Norman, Note 2) were used in the simulation. Such values for the unnegated forms of four adjectives could not be located. For these adjectives, the complement of the scale value for the negation was used. Referring to Figure 1, a false response to a negation has the same interpretation as a true response to the original. This has an important bearing on the

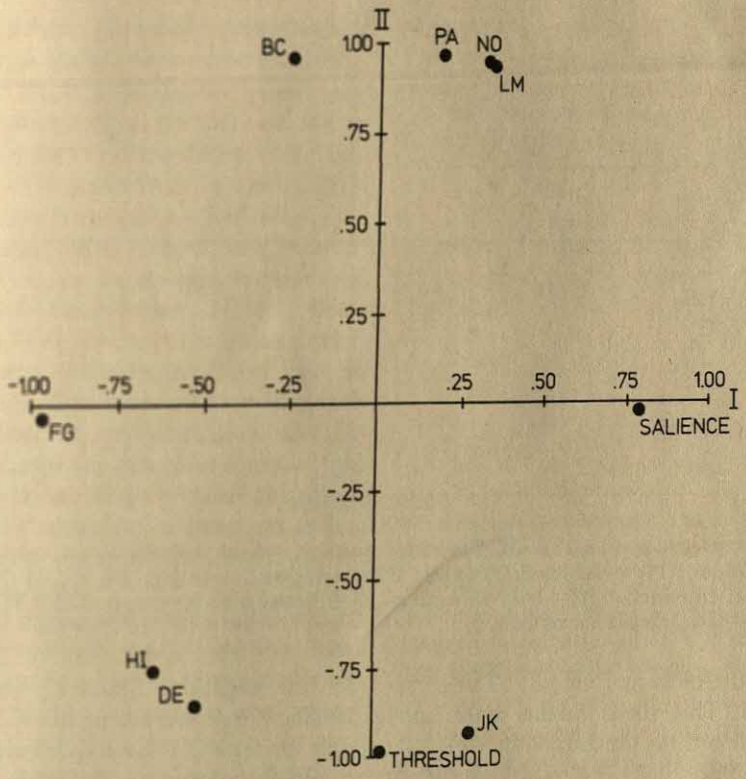


Figure 2. Plot of first two principal components from computer simulation. (PA = Ambitious-Dominant. BC = Arrogant-Calculating. DE = Cold-Quarrelsome. FG = Aloof-Introverted. HI = Lazy-Submissive. JK = Unassuming-Ingenuous. LM = Warm-Agreeable. NO = Gregarious-Extraverted.)

interpretation of the Wiggins results, as it requires the complementation of the predicted responses. It will be demonstrated that this can be interpreted as accounting for the second principal component.

Two principal components were extracted from the correlation matrix for the "responses" to the items of eight scales of the 500 hypothetical respondents. Two components accounted for 94.4% of the variance. These are plotted in Figure 2. A comparison with the Wiggins figures indicates a very similar structure. The differences consist of an overlap of NO and LM and a different ordering of the DE-FG-HI triad. It should be noted that the salience parameter loads highly on Factor 1 and the threshold parameter has a substantial loading on Factor 2. The strikingly similar pattern of results suggests that processes underlying the threshold model provide a plausible interpretation of the Wiggins data.

The precise interpretation of the two dimensions underlying the Wiggins data is facilitated by an examination of the properties of his scales. Wiggins does call attention to what he terms the "confound" between desirability and his scales, but the extent of this relationship is of some interest. First, note that in Figure 2 the four scales having the least desirable content (BC, DE, FG and HI) have substantial negative loadings, whereas the other four scales have neutral or positive loadings. In addition, a slight (approximately 30°) orthogonal rotation of the axes for the data shown in Wiggins' Figure 4 will give a complete separation of the scales high and low in social desirability. This, combined with the high loading of the salience parameter on this factor, would argue for an interpretation in terms of social desirability. Figure 3 presents a plot of the average desirability scale values and the scale means for ratings of accuracy of self-description as obtained from Norman

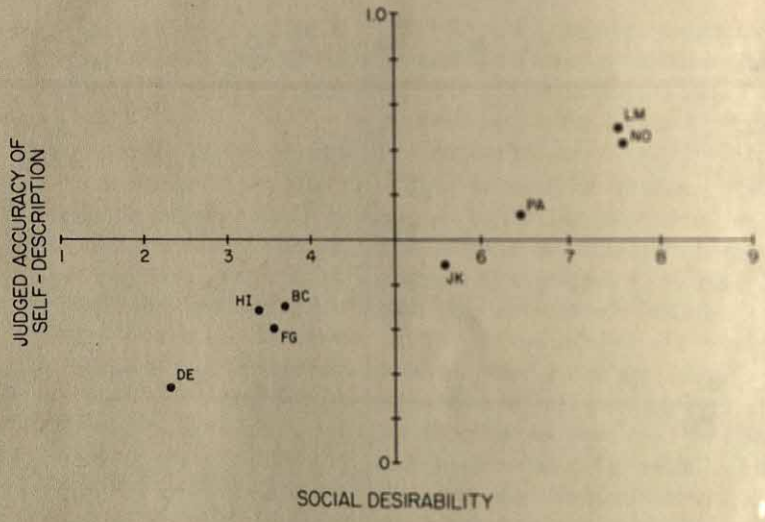

Figure 3. Correlation of social desirability scale values and judged accuracy of self-endorsement for Wiggins' scales. (PA = Ambitious-Dominant. BC = Arrogant-Calculating. DE = Cold-Quarrelsome. FG = Aloof-Introverted. HI = Lazy-Submissive. JK = Unassuming-Ingenuous. LM = Warm-Agreeable. NO = Gregarious-Extraverted.)

(Note 2) and Goldberg (Note 3). The correlation is .98. This sheds further light upon the interpretation of the first principal component. It implies that the average respondent is sensitive to the mean desirability of the adjectives and that these desirability scale values are colinear with the probability of the average respondent's endorsing items on the different scales. But some respondents are more sensitive than others to desirability (Jackson & Messick, 1969). High scorers on the first principal component are thus those who show higher relationships between their own probabilities of responding to an item and the item's judged desirability. Low scorers on the second principal component respond less in terms of the desirability scale values of the items.

The second principal component appears to reflect the differential tendency to endorse traits as self-descriptive (cf. Bentler, Jackson, & Messick, 1971; Morf & Jackson, 1972; Voyce & Jackson, 1977) and is dependent upon the presence of negations in the Wiggins traits. Table 1 presents the number of negated items on each scale together with the loading of the scale on the first principal component in the simulation study and average loadings from Wiggins (1979). When the simulation was undertaken without the special provision for the negations described above, negative loadings disappeared, along with the circumplex structure. It is hypothesized that they would also disappear in Wiggins' data, had he not chosen negations to comprise the majority of items in the scales forming the lower part of the circumplex. An examination of Figure 1 illustrates how, in terms of the threshold model, endorsing an item at a given level of desirability yields a negative correlation with the endorsement of a negated item at the same level of desirability. Those who endorse many traits as self-descriptive at a given level of desirability will tend to reject many negations at the same level of desirability. Since Wiggins engaged in item selection for the purpose of confirming a hypothesized structure, it is possible that his inclusion of many negations (even highly contrived ones like "uncrafty," "unwily," and "warmthless") for the lower two quadrants was dictated by the fact that the inclusion of such negations was necessary for obtaining the circumplex structure.

Plausibility of a Content Interpretation to the Circumplex

Although the findings in the simulation are very similar to the data reported by Wiggins, the success of the simulation does not *prove*

that the hypothesized threshold processes are operating, particularly since the simulation results do not duplicate Wiggins' results exactly. These differences may in part be due to differences between the desirability of an adjective when it is judged on its desirability and its desirability when an individual attributes the adjective to himself (see Jackson & Helmes, 1979), or to changes in adjective desirability since the Norman (Note 2) data were obtained. The forcing of a linear model onto a nonlinear situation may also have a bearing upon the differences between Wiggins' results and those of the simulation. But in weighing the competing interpretations of the data, it would be useful to consider the plausibility of the evidence as it bears on a denotative content interpretation of the two principal components.

Ever since Thurstone's pioneering work in the 1930s in multiple factor analysis, the weight of opinion has been in the direction of seeking evidence for the existence of characteristics of intellect or personality in the form of *simple structure*, that is, of identifying a resolution of test vectors such that a few tests defining a factor had high loadings, with the remainder loading negligibly. There are now literally hundreds of studies in the personality area confirming the applicability of the Thurstonian approach, that is, of expecting separate factors for each trait, defined by some analytic or judgmental criterion of simple structure. It is true that circumplexes such as those reported by Wiggins have been reported by others (Benjamin, 1974; Leary, 1957; Schaefer, 1959; Stern, 1970), but in all of these studies the potential role of response or judgmental styles was uncontrolled. Given the independence of our present simulation study, as well as that of Rogers (1971), from any particular content, it would be expected that the results of the above authors could just as easily have been simulated using parameters derived from the threshold model. On the other hand, when response styles were explicitly investigated, circumplexes consistently appeared (Jackson & Messick, 1961, 1962a, 1962b; Jackson & Pacine, 1961; Voyce & Jackson, 1977). Jackson (Note 1) found that 28 MMPI "scales" devised by ranking all 560 items in terms of judged desirability and keying alternate 20 item sets "true" and "false" yielded a regular, replicated circumplex array. True keyed scales formed a regular "fan" array from least to most desirable, all with positive loadings on the second factor, whereas false keyed scales also formed a similar regular array, but with negative loadings on the second factor. Voyce and Jackson (1977) showed that these findings did not depend upon use of MMPI items and could be obtained with frequency of endorsement scale values as well as with those for desirability. When the role of response biases is curtailed in personality assessment, however, as with the Personality Research Form, simple structure, rather than a circumplex, has been reported (Nesselroade & Baltes, 1975; Stricker, 1974).

Table 1
Number of Negated Items in Wiggins Scales, Loadings on Second Principal Component of Simulation, and Average Loadings on the Corresponding Wiggins Component

Scale	No. of negated items	Loading on first component	*M* loading from Wiggins (1979)
PA	0	.98	.81
BC	0	.96	.44
DE	11	−.85	−.14
FG	7	−.04	−.61
HI	11	−.73	−.79
JK	16	−.94	−.53
LM	0	.94	.07
NO	1	.94	.55

Note. All scales have 16 items. The data on the actual loadings were kindly made available to us by Wiggins. PA = Ambitious-Dominant. BC = Arrogant-Calculating. DE = Cold-Quarrelsome. FG = Aloof-Introverted. HI = Lazy-Submissive. JK = Unassuming-Ingenuous. LM = Warm-Agreeable. NO = Gregarious-Extraverted.

There is an important reason why traits should define independent, distinct, uncorrelated factors—such traits are more likely to yield evidence of convergent and discriminant validity. With all traits arrayed in only two dimensions and in general showing substantial correlations, it is unlikely that they would meet any of the Campbell and Fiske (1959) criteria for multitrait–multimethod validity.

In fact, before proffering or accepting the circumplex structure as a framework for understanding the content of personality, it would be appropriate to investigate and confirm the heteromethod convergent and discriminant validity of the vectors in such a space. Our own view, consistent with the findings of Jackson and Lay (1968), Kusyszyn and Jackson (1968), Morf and Jackson (1972), and others, is that the discriminant validity of traits is to be found, if at all, in the *residual* factor scores, after removing the influence of the two large principal components. In this sense, the reliabilities of individual scales reported by Wiggins can be regarded as spurious, representing not what is uniquely relevant to a given trait but what it shares with other traits. In the case of the Wiggins' data, each scale score is largely predictable from the others. A concept of *differential reliability*, as opposed to classical reliability, would distinguish the contribution to reliability of general factors, due to method and global content variance, from those due to unique trait variance.

But what is one person's method variance may be another person's trait variance (Campbell & Fiske, 1959; Jackson & Messick, 1958). The identification of two broad dimensions relevant to presentation of self may be considered an important and general finding of wide relevance to human functioning, including such diverse areas as psychopathology, socialization, and interpersonal influence. Wiggins has contributed importantly by calling attention to these dimensions, but we wish to emphasize the relative independence of these dimensions from particular trait-relevant stimuli. By an appropriate selection of stimuli and negations, Wiggins' structure could be changed dramatically. Putting one's best foot forward can be done within limits in the context of a variety of traits, and the desirability of behaviors relevant to particular traits can be manipulated. So let us not confuse content and style. (And let it not be said that we maintain that the Wiggins scales are devoid of content variance. Wiggins has confounded content and style). Both are crucial in understanding personality, but these concepts are not interchangeable. This issue might be resolved by identifying a new set of adjectives, each substantively linked to the individual scales but diverse in desirability. Half of the items should be worded positively, and the remaining, negatively. With the addition of marker scales for desirability responding, content and style factors might be distinguished, particularly if a sufficient diversity of desirability among items within each scale could be identified.

In a more general sense, in addition to methodological and empirical reservations, we are not impressed with the psychological or personological import of the circumplex. Despite what ancient philosophers have observed about perfect geometric figures, we doubt its explanatory value. Personality is almost certainly more complex than that which can be represented realistically in a two-dimensional plane. Even when considering only the interpersonal domain, such representations, although perhaps seductive in their simplicity, can hardly be expected to do justice to the subtlety and multiplexity of the variety of behavior. Similarly, although there is indeed diversity in the words used to describe traits, we would prefer to go beyond single words and use, among other things, larger units of the natural language as it has evolved over thousands of years, to define and to assess personality characteristics.

Externality as a Function of Obesity in Children: Pervasive Style or Eating-Specific Attribute?

Philip R. Costanzo and Erik Z. Woody
Duke University

The developmental sources of the link between stylistic externality and food-related externality found in the obese by Schachter and others were explored by testing whether the externality phenomena that have been found to differentiate obese and normal adults are also discriminators of obese and normal children. The results suggest that obese children as young as 7–12 years of age show an external responsiveness to salient food cues but not yet a generally external perceptual style. The implications of these findings for the development of obese externality are examined.

The most influential and intuitively appealing theory concerning the distinctive psychogenic characteristics of obese eating has been advanced by Schachter and his associates (cf. Schachter & Rodin, 1974). Stated most simply, Schachter's theory consists of two relatively independent hypotheses: (a) The eating behavior of the obese is less influenced by internal physiological cues signaling satiety or hunger (e.g., blood sugar level, gastric motility, etc.) than that of normal weight individuals, and (b) the eating behavior of the obese is more influenced by salient external cues (e.g., time of day, the taste and ready accessibility of foods, etc.) than that of normals. Although both of these hypotheses have met with fairly convincing confirmation in the research of Schachter and his colleagues (see Schachter & Rodin, 1974), it is the second hypothesis that has stood the test of independent replication (cf. Johnson, 1970; McArthur & Burstein, 1975; Nisbett & Gurwitz, 1970).

In attempting to provide a clear theoretical explanation for the externally moderated eating style of overweight individuals, Schachter (1971) has advanced the broad hypothesis that *any* stimulus (food related or not) above a certain intensity level is more likely to evoke a response from an obese than from a normal weight subject. In short, Schachter has argued that the externality evident in the eating behavior of the obese is only one manifestation of a pervasive external style. A number of studies support this broader hypothesis. Obese subjects show faster disjunctive reaction times, better short-term recall and lower tachistoscopic recognition thresholds than normal weight subjects do (Rodin, Herman, & Schachter, 1974), indicating a greater tendency for a salient stimulus to trigger a response in the obese. In addition, both the time estimations (Pliner, 1973; Rodin, 1975) and reaction times (Rodin, 1973) of the obese are more responsive to salient external–contextual cues than are similar responses of normals. Finally, there is evidence that obese individuals are significantly more field dependent on Witkin's rod–frame test (RFT) than normals are (Karp & Pardes, 1965; McArthur & Burstein, 1975), indicating a dispositional dependence upon salient contextual cues for the obese.

The correspondence between general external hyperreactivity and food related externality found in the obese led Rodin and Slochower (1976) to propose that externality

We would like to express thanks to the personnel of North Elementary School, Roxboro, North Carolina, for their help with this project and to Professor Irving Alexander for stimulating our thoughts on the questions raised in this article.

in general style leads to overeating, which in turn leads to obesity. In testing the plausibility of this causal sequence Rodin and Slochower (1976) performed a study that assessed environmentally mediated weight gain among preadolescent and adolescent normal weight girls who varied in general external responsiveness. More specifically, Rodin and Slochower used multiple assessments to classify 9–15-year-old camp-bound girls on external responsiveness. They predicted that the more external girls would evidence greater weight gain contingent upon the shift occasioned by an 8-week summer camp experience in a food-rich novel environment.

The findings were equivocal with respect to the primary hypothesis. Instead of finding a linear relationship between stylistic externality and weight gain, Rodin and Slochower found a nonmonotonic relationship between these variables. Thus, both the weight gainers and weight losers were found to be more external on the premeasured index than those girls whose weights remained stable across the 8-week experience. The obtained results were quite similar for the small contingent of overweight campers included in the sample. What one might conclude from the Rodin and Slochower study is that among a sample of normal weight girls one can predict weight change (but not simply weight gain) with a modicum of accuracy. Yet these data fall short of providing evidence for the causal role of generalized externality in producing environmentally mediated overeating.

In the current investigation we have addressed questions that are similar to those inquired about in the Rodin and Slochower study. That is, the current study has endeavored to examine the relative plausibility of the potential sources of the stylistic externality – food-related externality link suggested by Schachter's viewpoint and by the past research literature. It was felt that an important first step in examining the role of generalized externality in obesity would involve discerning whether obese children when compared to normal weight children would exhibit enhanced responsiveness to both external food-related cues and external nonfood cues when exposed to the kind of experimental arrangements which have characterized the research using adult samples. This strategy of inquiry introduces a broader developmental perspective on the issue of causal determination of the eating style of the obese than is evident in work such as Rodin and Slochower's study.

If general externality is a predisposing style resulting in overeating and obesity, then one should expect that children who are already obese will evidence greater external hyperreactivity than their nonobese counterparts will. This proposal, of course, presumes that childhood obesity is continuous with obesity in adulthood. The evidence would appear to justify such a presumption. A number of studies have indicated that those who are obese in childhood tend to remain obese through adulthood (Heald & Hollander, 1965; Knittle, 1972; Mullins, 1958; Rimm & Rim, 1976; Rose & Mayer, 1968). In adult follow-up studies of earlier childhood public health examinations (Abraham, Collins, & Nordsieck, 1971; Abraham & Nordsieck, 1970) it was found that 86% of overweight boys and 80% of overweight girls became overweight adults, against 42% of average weight boys and 18% of average weight girls.

An extremely poor prognosis for juvenile-onset obesity was given by Stunkard and Burt (1967), who empirically estimated that the more than 4–1 odds against an obese child becoming a normal weight adult rise to 28–1 if weight reduction does not occur by adolescence. Finally, it is important to note that the primary source of obese subjects used in adult inquiries into general and food specific externalities have been college-aged young adults (19–22 years of age). According to Grinker's (1973) criterion, which because of juvenile lipid cell development sets age 19 as the dividing line between obesity of juvenile onset and that of adult onset, most previous laboratory studies of obese externality are most likely to have used samples of subjects characterized by juvenile onset of overweight. Thus, although a definitive but expensive longitudinal study exploring the developmental vicissitudes of external responsiveness in obese individuals would be highly desirable, a study probing both general and

food-specific externalities in obese children would seem to warrant cross-sectional comparisons with the findings from methodologically similar adult inquiries, since the overlap in childhood and young adult obese populations appears to be quite substantial.

Accordingly, the current study posed three primary questions: (a) Is there a differential dependence on external food related cues for obese versus normal weight children? (b) Is there a differential dependence on and responsivity to external perceptual and cognitive processing cues for obese versus normal children? (c) Is there a relationship between a child's dependence upon external cues in the eating process and his dependency upon external cues in the perceptual–cognitive area?

The differential responsivity to food-related external cues by obese and normal children was examined in the current study by manipulating the accessibility of food. The specific manipulation used was derived from the work of Schachter and Friedman (1974) and McArthur and Burstein (1975). In both of these studies, obese and normal subjects were presented with either shelled *or* unshelled nuts to nibble on. In accordance with externality theory, both studies convincingly demonstrated that obese subjects eat significantly fewer nuts with shells on than with shells off, whereas the ad lib nut eating of normals is largely unaffected by the presence of a shell.

In order to examine differences in non-food-related externality between obese and normal children, two assessments were made. The first consisted of Witkin's rod–frame test of field dependence; the second was a measure of obese and normal children's differential estimations of the elapsed time of a boring versus an interesting film. The RFT measure had been used in the McArthur and Burstein study. As noted above, McArthur and Burstein found that obese subjects ate significantly fewer unshelled nuts than their normal weight counterparts did. These same subjects were assessed for field dependence on the RFT task, and it was found that obese subjects were significantly more field dependent than normal weight subjects were. More important, it was found that external food related behavior was significantly related t degree of field dependence. That is, McArthu and Burstein found a quite significant corre lation ($r = -.58$) between the number o unshelled nuts eaten and RFT-assessed fiel dependence. Furthermore, McArthur an Burstein found a sizable correlation ($r = .62$ between percentage overweight and degree o field dependence. Since these findings consti tute the strongest and clearest support for th link between perceptual–cognitive externalit and food-related externality, McArthur an Burstein's experimental arrangements wer replicated with 7–12-year-old children in th current study. Because past longitudinal stud ies of field dependence and psychological differentiation (cf. Faterson & Witkin, 1970) have indicated that the RFT is both reliable for children and is evidenced by cross-aged stability, it appeared reasonable for use with a childhood sample.

Obese and normal children's estimations of the elapsed time of a boring versus an interesting film (shown in the presence of a bowl of either shelled or unshelled nuts) were used as a second measure of generalized externality because it has been cited by Leon and Roth (1977) as the single strongest evidence for generalized externality differences between obese and normal weight individuals. Both Pliner (1973) and Rodin (1975) have demonstrated that obese estimates of time elapsed are significantly more affected by interest cues in the surrounding environment than are the time estimates of normal weight individuals. The current study partially derives from the Rodin (1975) investigation, which very clearly demonstrated that obese subjects tend to overestimate the length of time of a boring tape and underestimate the length of time of an interesting tape, whereas the difference in time estimation of the boring and interesting tapes for normals is not significant.

In summary, the current investigation has endeavored to discern whether the externality phenomena that have been found to differentiate obese and normal adults are also discriminators of obese and normal children. The externality view of obesity suggests a strong

causal relationship between general and food-specific externality. It is believed that the developmental continuity or discontinuity of the adult phenomena in a sample of children with a high probability of maintaining an obese adjustment into young adulthood will help to provide data on the plausibility of the application of this causal assumption to the life span.

Method

Design Overview

The experiment proper was run in two parts. In the first part obese and normal children were asked to watch and rate either a boring or an interesting film of 10 minutes' duration while in the presence of a large bowl of either shelled or unshelled peanuts. This arrangement yielded a 2 (Weight Group) × 2 (Film) × 2 (Shelled–Unshelled Nuts) between-subjects factorial design. The dependent measures assessed were (a) the amount of ad lib eating of peanuts, (b) the subjects' estimate of the time taken by the observed film, and (c) the subjects' rating of the interestingness of the observed film.

For the second part of the study, all children were individually escorted to a darkened room and were administered eight trials of Witkin's rod–frame measure of field dependence–independence. These data were evaluated in a 2 (Weight) × 2 (Sex) factorial design. In addition to the analyses of variance on the separate dependent variables, correlations were computed (within and across sex and weight) among percentage overweight, quantity of nuts consumed, and field dependence.

Subjects

Subjects were drawn from the second through fifth grades of North Elementary School, a Roxboro, North Carolina, school of about 350 children. A sample of 56 males and females (28 predesignated obese and 28 predesignated normal weight) was run through the several conditions of the study. The initial sample was selected through teacher nomination. Teachers were asked to indicate which children in their class appeared distinctly overweight, which appeared normal weight, and which appeared distinctly underweight. From their nominations, groups of 28 obese and 28 normal weight subjects were assessed on three measures under the conditions indicated above: (a) their eating of shelled or unshelled nuts, (b) their time estimations of the length of a boring or interesting film, and (c) their RFT-measured field dependence. Inclusion in the final sample of subjects was determined by the subjects' actual measured deviation from average weight for age and height and not the teacher rating. Because of the instability of weight in growing children (Garn, Clark, & Guire, 1975), a 25% overweight *minimum* criterion was used for classification of an overweight subject. The criterion for inclusion as a normal weight subject was that the child fall between −10% and 10% deviation from average weight for age and height. Children were weighed and measured in the school's annual health screening, which was fortuitously scheduled 1 week after the completion of our study. Of the 28 teacher-referred overweight children, only 1 failed to meet our minimum criterion for inclusion in the sample. The 27 overweight children included in the final sample ranged from 25% to 124% overweight for their age and height (the National Center for Health Statistics, 1970, studies were used for purposes of comparing our sample children to national averages). On the average the 27 overweight children in the experimental sample were 48.8% overweight, with a range of 40.8% to 52.7% overweight in the four Shelled Nut–Unshelled Nut × Boring Film–Interesting Film cells of study. The average age of the overweight children was 10.0, with a range of 9.7 to 10.5 in the four experimental cells. The average height of the overweight groups was 57.8 inches (1.47 m; cell means ranged from 57.2 inches to 58.1 inches, or 1.45 to 1.48 m). Finally, the average weight of the obese sample was 118.2 lbs. (cell means ranged from 115.0 to 124.6 lbs).

Teachers were not quite so accurate in their normal weight referrals. Of the 28 subjects designated as normal weight, 20 approximated our a priori criterion of between −10% and 10% deviation from normal weight. The 8 subjects discarded from the normal weight experimental cells included 2 children who were appreciably underweight (−17% and −18% below average weight) and 6 subjects who were of borderline overweight status (14% to 24% overweight). The final sample of normal weight subjects ranged from −12% to 8% deviation from average age/height weight. The mean deviation from average weight for the normal sample was −2.3% (with a range of −4.6% to 1.1% across the four experimental cells). The average age of the normal weight sample was 10.0 years, with a range of means of 9.5 to 10.7 in the experimental cells. The average height and weight of the normal weight sample were 56.1 in. and 73.1 lbs., respectively (with a cell mean range of 55.4 in. and 69.3 lbs. to 57.0 in. and 77.8 lbs.). Although the 7 discarded mild to moderately overweight subjects (the 6 who had been teacher designated as normal weight and 1 who had been teacher designated as obese—but whose objective weight status was not found to correspond to teacher rating) were excluded from the univariate analyses comparing obese with normal children on the primary dependent measures, their data were included in appropriate correlational analyses using percentage overweight as a criterion measure. Thus, the correlational analyses contained 54 subjects whose weights varied continuously from −12% to 124% deviation from average weight.

Procedure and Materials

One experimenter escorted each subject from his classroom to the trailer and introduced him to a second experimenter in the trailer. The second experimenter asked the subject to take a seat. This seat faced both a projection screen and a table upon which was a bowl of peanuts, shelled or unshelled, according to the assigned condition. This table was lit by three 40-watt incandescent lights. These provided enough illumination to make the bowl of nuts salient but not so much as to obscure the projected image.

In the nuts-with-shells condition, the fragments of three emptied shells were in the bowl. The second experimenter said, "We're trying to see what kids think of different kinds of movies. We'd like to show you a movie and then get your opinion of it, OK? Help yourself to some nuts. I'll be back when the movie is over." Meanwhile the experimenter had shelled a couple of nuts in the nuts-with-shells condition. In either condition he left, munching a couple of nuts. The movie was projected through the open door of the two adjoining rooms. The projection distance was about 10 feet (3.05 m), making a rather small but bright and easy-to-see image. Subjects were then shown an interesting or boring film. For the "interesting" condition, *Toot, Whistle, Plunk and Boom*, a 10-minute Disney cartoon about the origin and development of musical instruments, was shown. For the "boring" condition, 10 minutes of *The Right of Age*, a child-educational film dealing with protective services available for the aging, was shown.

At the end of the film the experimenter returned and asked three questions. For the first question the subject was presented with a clock face with movable hands and was asked, "How long did the movie seem to take? Would you like to show me on this clock face? Here's the time we started—now what time would you think it is now? I want your impression of how much time went by." Subjects with wristwatches were asked not to look at them until they had guessed. If the subject got the two hands mixed up or had some other readily apparent difficulty, the experimenter assisted him a bit. The second question was, "How much do you think other kids would like this movie?" The subject's response to to this question was recorded on a 6-point scale ranging from "dislike a whole lot" to "like a whole lot." The third question asked, "Was this movie interesting to you?" Again the response was recorded on a 6-point scale ranging from "very boring" to "very interesting."

Following these queries, the first experimenter escorted the subject to the school's health room. Outside this room he explained to the subject that inside it would be dark and all he would see was a square lit up with a stick inside it. He was told that the task was a game, the object of which was to make the stick "go straight up and down, like the walls of a building or a flagpole outside. You will have some buttons which make the stick move." Then the experimenter held a ruler at an angle an asked the subject to make it straight up and dow Invariably the subject immediately repositioned th ruler to vertical.

The subject was blindfolded, led into the com pletely darkened room, and seated in a chair abou seven feet in front of the rod-and-frame apparatu The rod-and-frame apparatus was modeled after th of Witkin and his associates (1962) and consisted an outline square 40 inches (1.02 m) on each si within which was centered a 38-inch (.97 m) ro The rod and frame could be tilted independently and their respective degrees of tilt read off a pro tractor at the back of the apparatus. A variac wa used to limit the brightness of luminescent panel on the rod and frame, so that in a dark room onl the illuminated outline square and rod could be see The degree of tilt of the frame could be controlle manually by the experimenter, whereas the degre of tilt of the rod could be controlled remotely b the subject through push buttons that operated motor. After a brief period of dark adaptation, th subject's blindfold was removed and he was aske to make eight judgments of verticality. On half o the trials the frame was tilted 28 degrees to the right and on half it was tilted 28 degrees to the left, thu generating four combinations of rod-and-frame tilt Each combination was presented twice in random order. After each trial the subject was told to clos his eyes while the experimenter used a flashlight t record the degrees of deviation of the rod setting from vertical and to set the rod and frame at th appropriate tilt for the next trial. The averag degrees of deviation from vertical placement of th rod for the eight trials constituted the measure o field dependence. Finally, the subject was thanked and was returned to his classroom.

Results

Eating Behavior

A $2 \times 2 \times 2$ (Weight × Film × Nut) analysis of variance was performed on log grams of nuts consumed by the children. There were two significant effects that emerged from this analysis. First there was a main effect for nuts, indicating that a greater quantity of nuts without shells were consumed than nuts with shells, $F(1, 39) = 9.15$, $p < .01$. There was also a significant Weight × Nut interaction, $F(1, 39) = 4.94$, $p < .05$, which qualified the nut main effect. Table 1 presents the means involved in the interaction. Both actual grams of nuts consumed and log grams of nuts are represented on this table. It is clear from even a casual perusal of the means presented in this table that the presence or absence of shells on the nuts exerted a much stronger effect on the consumption of obese children

Table 1
Nut Consumption as a Function of Weight and the Presence of Shells

Condition	Normal			Obese		
	Log grams	Grams	*n*	Log grams	Grams	*n*
Shells off	1.06	18.97	11	1.47	43.50	13
Shells on	.94	11.07	9	.67	6.29	14

than on the consumption of normal weight children. Simple effects analysis shows that for obese subjects the presence of shells very significantly depressed consumption in comparison to the shells off condition, $F(1, 39) = 16.94$, $p < .001$, whereas for normal weight subjects the presence of a shell had an insignificant effect on nut consumption, $F(1, 39) < 1$. The type of film (i.e., boring or interesting) had no influence on eating behavior, either as a main effect or in interaction with the other independent variables.[1]

In summary, then, these data provide a very convincing case for the early entry of externality effects in the eating of the obese. The obtained results of this study compare very favorably with those of the Schachter and Friedman (1974) study and the McArthur and Burstein study (1975). A more articulated comparison of these data and McArthur and Burstein's nut-eating data will be taken up in the discussion.

Field Dependence: Judgments of Verticality

The 2 × 2 (Weight × Sex) analysis of variance on subjects' RFT judgments revealed no effects whatever for either weight, sex, or the Weight × Sex interaction. In fact, all *F*s were less than 1.

Nonetheless, inspection of within-cell correlations revealed a consistent pattern of results. In spite of the lack of significant difference in field dependence between obese and normal subjects, the correlation between percentage overweight and RFT assessed field dependence for the total sample of 54 was significant, $r(52) = .33$, $p < .02$. However, the major source of this correlation was within the obese sample itself, $r(25) = .50$, $p < .01$, and it was not significant for the normal weight subjects, $r(18) = .14$, $p < .20$. Hence, only for obese children was field dependence quantitatively related to degree of overweight, and field dependence appears unrelated to the qualitative distinction between overweight and normal weight.

The Relationship Between Eating Behavior and Judgments of Verticality

The negative correlation previously reported by McArthur and Burstein between

[1] Given that the sample of children used in the study varied on age and sex dimensions, it was important to discern whether either of these variables accounted for the obtained results. First of all, the sex distribution approximated a 50–50 split within the Shells × Weight experimental cells. Each of the three cells containing an odd number of subjects (see Table 1) was comprised of one more female than male subject, whereas the remaining cell contained the same number of males and females. Similarly, the ages of subjects were reasonably homogeneously variant within cell; the range of age standard deviations in the four Weight × Shells experimental cells was .91 to 1.37. Despite this equivalence of distribution by sex and age, it was felt necessary to rule out statistically the effects of both age and sex as qualifiers of our results. Accordingly, three analyses were run. The first of these analyses was a 2 × 2 × 2 (Weight × Shells × Film) analysis of covariance using age as a covariate and log grams of nuts consumed as the dependent measure. The Weight × Shells interaction and the shells main effect remained significant, Fs(1, 38) = 6.44 and 11.40, respectively. In addition, no other main effects or interactions emerged as significant. Secondly, a similar three-way analysis of covariance was performed using age *and* sex as multiple covariates. The results of this analysis were quite congruent with the first covariance analysis, Weight × Shells, $F(1, 37) = 6.27$, $p < .02$; Shells, $F(1, 37) = 11.15$, $p < .002$, with no additional effects significant. Third, a Weight × Shells × Sex analysis of variance was performed to test directly the impact of sex on the results. It was found that sex as a main effect yielded an $F < 1$ and that all three interactions of the experimental variables with sex yielded Fs < 1. Finally, reapportioning the sample by sex did not appreciably alter the Fs for the Weight × Shells interaction, $F(1, 39) = 4.49$, $p < .04$, nor for the shells main effects, $F(1, 39) = 12.32$, $p < .001$. A similar absence of age and sex effects was found in the case of the time estimation and field dependence measures. Neither sex nor age used as covariates nor sex used as an independent variable changed the pattern of reported results. In view of the lack of significant variance accounted for by age and sex of the child, collapsing the sample on these variables appeared warranted.

Table 2
Mean Time Estimations (in Minutes) of the Boring Versus Interesting Film by Obese and Normal Children

Group	Film	
	Interesting	Boring
Obese	19.79	16.02
Normal	24.80	13.43

subjects' field dependence on the RFT and log grams of nuts with shells consumed was not found with this sample of children. For all subjects run in the shells on condition, including those excluded from subject groups in the analysis of variance, this correlation was insignificantly positive, $r(25) = .08$. The correlation failed to approach significance, or even to take a negative sign, for any group of subjects—females, $r(14) = .04$; males, $r(13) = .15$; obese subjects 20% overweight, $r(14) = .27$, and normal weight subjects, $r(9) = .05$. The correlation between field dependence on the RFT and log grams of nuts without shells consumed was also insignificantly positive for all subjects run in the shells off condition, $r(29) = .28$, as well as for each group of subjects—females, $r(14) = .05$; males, $r(15) = .38$; obese subjects 20% overweight, $r(13) = .23$; and normal weight subjects, $r(11) = .22$. In summary, no evidence whatever was found to support the prediction that eating behavior would be related to field dependence scores on the RFT.

Time Estimation

A $2 \times 2 \times 2$ (Weight × Film × Nut) analysis of variance was performed on subjects' estimations of the duration of the film. The type of film (boring or interesting) yielded a highly significant main effect, $F(1, 39) = 13.25$, $p < .001$. Subjects estimated a longer duration for the interesting film ($M = 22.29$ minutes) than for the boring film ($M = 14.73$ minutes), even though the real duration of both films was the same (10 minutes).

A marginally significant Weight × Film interaction was also found, $F(1, 39) = 3.35$, $p < .10$. Although the marginality of this effect warrants some interpretive caution, it may be seen from Table 2 that the difference in time estimations for type of film appears somewhat more pronounced for normal subjects than for obese subjects. In fact, the difference was highly significant for normal subjects, $F(1, 39) = 12.77$, $p < .001$, but insignificant for obese subjects, $F(1, 39) = 1.98$, $p > .10$. Hence there is a tentative suggestion that the time judgments of obese subjects were *less* affected by interest cues than were those of normal weight subjects.

Film Ratings

The children's ratings of the interestingness of the two films were assessed in two 2(Weight) × 2(Shells) × 2(Film) analyses of variance. The first analysis was performed upon subjects' responses to the question: "How much do you think other kids would like this movie?" Whereas the second analysis was done on the children's responses to the question: "How interesting was this movie to you?" Responses to the questions were given on a 1–6 scale of liking and interest level. For both questions, the main effect for type of film was highly significant, $Fs(1, 39) = 49.84$ and 40.79; $ps < .001$. Subjects indicated that "other kids" would like the movie used in the interesting condition "pretty much" ($M = 5.32$) and would dislike the movie used in the boring condition "a little" ($M = 3.05$). The subjects themselves found the movie used in the interesting condition to be midway between "pretty interesting" and "very interesting" ($M = 5.50$) and the movie used in the boring condition to be "a little interesting" ($M = 3.82$). These results indicate that the intended differentiation between the boring and interesting movie was successfully manipulated. Although all other effects and interactions for the "other liking" measure yielded $Fs < 1$, there was a surprising and interesting Weight × Film × Nut interaction, $F(1, 39) = 4.49$, $p < .05$, for the subjects' report of their own interest in the films. Inspection of the cell means (see Table 3) reveals that all groups rated the interesting film nearly the same (no significant differences). However, there was a significant Weight × Nut simple interaction for the boring film, $F(1, 39) = 6.47$, $p < .025$. The presence or absence of shells on the peanuts

affected the ratings of the boring film differently for obese subjects than for normal subjects. Looking at simple main effects, the difference did not reach significance for normal subjects, $F(1, 39) = 1.86$, $p > .20$, but it did for obese subjects, $F(1, 39) = 5.24$, $p < .05$. That is, the obese subjects rated the boring film as significantly more interesting when it was viewed in the presence of nuts without shells than when it was viewed in the presence of nuts with shells (shells off $M = 4.33$ or "a little interesting," whereas shells on $M = 3.21$, or "a little boring"). Thus, it appears that the presence of available and attractive food enhances obese children's interest in rather mundane non-food-related stimuli. It should be noted that no other effects from the $2 \times 2 \times 2$ analysis on self-rated interest even approached significance.

Discussion

Externality in Eating and Generalized Externality

The results of the present studies concerning the externality theory strongly support its hypotheses about food-related behavior but fail to give strong support to the hypothesis that food-related externality has its origins in a general external style for obese populations. Table 4 and Figure 1 present a detailed comparison of the McArthur–Burstein experiment with university students and the attempted replication with children. With regard to the eating behavior dimension of the experiments, it is evident that the overall magnitude and pattern of the original results are closely matched in the replication. However, in the McArthur–Burstein experiment, the interaction of weight with type of nut was found to occur because the presence of a shell reduced the likelihood of eating any nuts more for obese than for normal individuals. In the replication, the results were mainly due to the tendency for the shell to reduce the quantity of nuts consumed more for obese than for normal-weight eaters. Although this difference may merely be due to differences in the kind of nut used—almonds are hard to shell, peanuts easy—it is worth mentioning as the only real distinction between the eating behavior found in the two experiments.

Table 3
Cell Means for the Question, "Was This Movie Interesting to You?"

Film	Normal		Obese	
	Shells off	Shells on	Shells off	Shells on
Interesting	5.75	5.40	5.43	5.43
Boring	3.50	4.25	4.33	3.21

However, the respective results of the field-dependence dimension of the experiments are far less congruent. In the McArthur-Burstein experiment, there was a strong relationship between degree of overweight and field dependence for all female subjects but no such relationship for male subjects. By contrast, in the replication there was a strong relationship between overweight and field dependence for all obese subjects but no such relationship for normal weight subjects. Similarly, the strong relationship between field-dependent eating and field-dependent perception found in the original experiment was totally lacking

Table 4
A Comparison of the McArthur–Burstein Experiment With University Students and an Attempted Replication With Children

Item	McArthur–Burstein *r*	Replication *r*
Correlations between percent overweight and judgments of verticality		
All subjects	.62	.33
Obese females	.60	.45
Obese males	−.06	.57
Normal females	.41	.25
Normal males	.04	.13
Correlations between nut consumption and judgments of verticality		
Shells on	−.58	.08
Shells off	.25	.28
Correlations between percent overweight and nut consumption		
Shells on	−.45	−.42
Shells off	.09	.18

in the replication. Furthermore, the lack of any difference between obese and normal children in field dependence casts doubt on the hypothesis that externality is an obesity-disposing and long-standing generalized trait. Instead, it appears that developmentally early evidences of externality in the obese are confined to the eating circumstances.

Using the field-dependence results with children as evidence against the generality of externality as a trait may seem a bit thin. However, the results of the time estimation phase of the experiment are also clearly incompatible with the generalized trait formulation. In a very recent review (Leon & Roth, 1977) of externality theory and the evidence supporting it, it has been claimed that the studies on time estimation constitute the "greatest support for the external control theory" (p. 129) among non-food-related behaviors. Although these studies are somewhat contradictory methodologically, they do consistently report that the time estimation of the obese is more manipulable by external cues than is the time estimation of normals. However, in the present study with children, obese subjects' time estimation was somewhat *less* affected by the boring–interesting distinction than was normal subjects' time estimation. It would not seem that the failure to obtain the predicted Weight × Film Interest interaction could be accounted for by the irrelevance of the time estimation task for children. The direction of the significant main effect for film interest, $F(1, 39) = 13.25$, $p < .001$, is quite compatible with obtained results for this measure that have issued from studies of adult cognitive process. Thus the children in this study react to interest cues in time estimation quite similarly to adults. Yet, these interest-based distortions in time estimation were not found to be moderated by weight status in the manner suggested by a generalized externality hypothesis. This evidence, along with the field-dependence evidence, suggests that externality in response to food cues precedes other manifestations of externality in the obese child.

In contrast to the obese children's relatively low responsiveness to interest cues in the time estimation task, they exhibited an unanticipated responsiveness to food cues in the film ratings. For the obese children, the presence or absence of shells on the nuts appears to have influenced their affective experience of a relatively uninteresting movie. This result suggests that rather small variations in incidental food cues may have a considerable effect on how the obese child experiences an unrelated, fairly neutral stimulus. Although externality in obese children may be confined mainly to food cues, these cues may affect the obese child's experience and behavior in ways not closely related to eating.

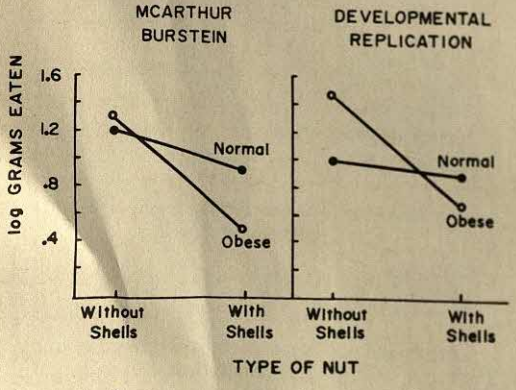

Figure 1. Log grams eaten by type of nut for McArthur–Burstein experiment and developmental replication.

Conclusions and Implications

The above-reported results lead to the summary conclusion that obese children as young as 7–12 years of age already show evidence of the externality in response to salient food cues that had been previously documented in adult obese samples. Yet, it does not appear that this external response style has clearly derived from general externality in this childhood sample.

There are at least two ways to view the discontinuities in the results of this study and prior studies of generalized externality in samples of obese young adults. One could plausibly maintain that the phenomena accompanying and accounting for childhood obesity are distinct from those that characterize obesity in adults. Given this perspective, the results of the current study would lead one to conclude that two different segments of

the obese population (i.e., children and young adults) have a common tendency to react differentially to salient versus nonsalient food-related cues. Further, the disparity between the evidence for non-food-related externality from the current study and past adult inquiries would suggest that both general externality and its relationship to overeating are distinctive characteristics of the adult obese.

Although such a descriptive distinction between two populations of obese individuals is interesting in its own right, previously cited studies documenting the population continuity between obese children and obese young adults (cf. Abraham & Nordsieck, 1970; Heald & Hollander, 1965; Rimm & Rim, 1976) would suggest that the differences found between the current child and past adult obese samples have implications for understanding the development of an obese behavioral adjustment.

From this vantage point it would appear that the causal priority of general externality in the overeating of the obese suggested by Schachter's perspective and directly proposed by Rodin and Slochower (1976) does not bear up well developmentally. The current data from a comparison sample of obese children indicate that the early instances of externality in juvenile-onset obese individuals are largely confined to the eating circumstance.

As an alternative to the proposal that implies a causal sequence that represents obesity resulting from overeating, and overeating resulting from stylistic externality, one might propose that the externality evident in the eating responses of the current sample of children is a function of their obesity and the later development of pervasive externality a consequence of generalization of eating style to other stimuli. Such a proposal makes sense when one takes account of the socialization practices that are likely consequences of a child's obesity. Owing to the deviant status of obesity in middle-class culture, childhood obesity is likely to arouse concern and resulting attempts to mediate weight loss by a variety of food restrictions. This kind of socialization strategy is likely to impose a norm of high restraint of eating responses on the child while simultaneously wresting control over the eating environment away from the child. Such directive parental constraint over a child's behavior has been shown to result in external control adjustments in a number of areas (e.g., Aronfreed, 1964; Baumrind, 1971; Becker, 1964). Aronfreed, for example, notes that strong restrictive control in a given behavioral domain both results in a poor internalization of controls and a sensitization to the stimuli in that domain of behavior. We would propose that the obese individual's food externality may be an instance of such a process of sensitization.

Although a proposal such as the one just presented is a digression from the data base of this study, it is compatible with our pattern of findings and does bear some linkage to at least one emerging framework in the study of obesity. Herman and his colleagues (Herman & Mack, 1975; Herman & Polivy, 1975; Hibscher & Herman, 1977) have proposed that the critical source of externality in the obese individual is his high level of restraint. Because the obese individual is deviant from a desired norm of physical attractiveness, he actively restrains food intake. Such restraint paradoxically renders food cues more salient and results in the stimulus-bound eating characterized by Schachter and others. Herman's results tend to confirm this viewpoint in that they demonstrate (Hibscher & Herman, 1977) that even normal weight restrainers are more likely to evidence external behavioral characteristics than are so-called unrestrained eaters. This might suggest that tracking the developmental origins of dietary self-restraint in the obese person's socialization history might be a fruitful direction for subsequent cross-sectional and longitudinal inquiries into the sources of obese externality.

Avoidance of the Handicapped: An Attributional Ambiguity Analysis

Melvin L. Snyder, Robert E. Kleck, and Angelo Strenta
Dartmouth College

Steven J. Mentzer
Medical School, University of Minnesota

We demonstrated a general strategy for detecting motives that people wish to conceal. The strategy consists of having people choose between two alternatives, one of which happens to satisfy the motive. By counterbalancing which one does so, it is possible to distill the motive by examining the pattern of choices that people make. The motive used in the demonstration is the desire we believe most people have to avoid the physically handicapped. Because they do not wish to reveal this desire, we predicted that they would be more likely to act on it if they could appear to choose on some other basis. In two studies we found that people avoided the handicapped more often if the decision to do so was also a decision between two movies and avoidance of the handicapped could masquerade as a movie preference.

This paper illustrates a general strategy for detecting motives that people wish to conceal. The strategy involves asking people to choose between two alternatives, one of which accidentally happens to satisfy the motive that we suspect is present but hidden. For instance, we think that most people wish to avoid contact with the physically handicapped but do not want to admit it. If we give a person a choice between sitting next to a handicapped person or sitting beside a normal one, he may choose the handicapped so as to conceal his desire to avoid. However, if we ask a person to choose between two movies, one of which apparently by accident happens to entail sitting next to a handicapped person, the other next to a normal, he can avoid the handicapped while appearing to exercise a preference for a movie. By having enough people make such decisions and by varying which movie is associated with the handicapped person, or more generally, by varying which of two alternatives happens to satisfy the suspected motive, we can see whether people consistently make choices that satisfy it. Thus, we would look for more frequent avoidance of the handicapped when there is a choice between the two movies than when there is not.

This strategy for detecting hidden motives was derived from correspondent inference theory (Jones & Davis, 1965). Jones and Davis (1965) are concerned with how the decisions that an actor makes inform us about his motives. We learn about the actor by looking at the effects his decision produces. Jones and Davis (1965) classify the effects of making decisions into two categories: common effects (those that result regardless of which alternative is selected) and noncommon effects (those brought about by selecting one alternative but not the other). Assume for example, that Sam has a choice between two roommates. Both like classical music but one likes to cook, whereas the other likes long philosophical discussions; in this case, classical music is a common effect, and good food and bull sessions are noncommon effects. Decisions

The authors thank William Bernstein, Mark Davis, Edward E. Jones, William N. Morris, and William Swann for useful comments on a draft of this article. This research was supported in part by National Institute of Mental Health Grant MH 29446 to Robert E. Kleck.

tell us nothing about a person's intentions with respect to common effects. In this case, Sam's decision can tell us nothing about his feelings toward classical music. However, decisions have the potential to inform us about whether noncommon effects are intended. They are most informative when the number of noncommon effects is low. In Sam's choice of roommates, there are only two noncommon effects: good food and bull sessions. If he chooses the roommate who likes long discussions, we are tempted to conclude that Sam likes bull sessions. But there is still some ambiguity. Perhaps Sam is trying to lose weight and is avoiding the good cook rather than seeking the philosopher. We could be more confident about Sam's motive if there was only one noncommon effect, for example, if the only difference between the roommates was that one liked long discussions and the other did not. The general rule is that the more noncommon effects there are, the more ambiguous the motives behind a decision.

Our strategy for detecting concealed motives can be understood in terms of correspondent inference theory. Again, we will use the handicapped example. When the choice is simply between sitting with a handicapped person or with a normal one, the handicap is the most salient noncommon effect. A decision to avoid strongly suggests the actor's intention. However, when the choice is between movies that are accidentally associated with sitting next to one person or the other, the two movies as well as the handicap are now noncommon effects, and the decision that happens to avoid the handicapped leaves the motive ambiguous. The actor can choose to avoid the handicapped person and claim to be exercising a movie preference because objectively there is no way to tell from a single decision. However, by having many people make such a decision and by counterbalancing which other noncommon effect, that is, which movie, is paired with the handicapped, we can see whether people do more frequently choose to avoid the handicapped person when doing so is one of several noncommon effects of the decision rather than the only noncommon effect.

This strategy can also be understood in very similar fashion by application of Kelley (1972) discounting principle. The principl states that "the role of a given cause in pr ducing a given effect is discounted if oth plausible causes are also present" (p. 10 For example, we are less confident that t choice of a person to date is based on t person's intelligence if the person possess other features such as physical attractivene that are plausible causes for the choice. making the choice between handicapped a normal persons also a choice between movie we allow discounting of the role that t handicap plays in the decision. With t introduction of other plausible causes, t motives behind a decision are obscured. W the researchers, can discover the real moti by employing another of Kelley's principles– the covariation principle: "An effect is attri buted to the one of its possible causes wit which, over time, it covaries" (Kelley, 197 p. 3). We can see whether movie choic covaries with avoidance of the handicappe or, more generally, whether behavior covarie with satisfaction of the unacceptable motiv

To demonstrate the utility of the gener strategy that we have outlined, we decide to examine the motive we used in the exampl above. That is, we decided to test whethe people are motivated to avoid the handicappe but are unwilling to acknowledge tha motive. Being around the handicapped seem to make people feel uncomfortable. (Kleck 1966, 1968). There are a variety of reason why this might be so, for example, fear of th unknown, uncertainty about how to respon or perhaps the reminder that the handicap provides of our own mortal physicality (Becker, 1973). At the same time, few handi capped people do anything to deserve thei fate, and we may believe that we should treat the handicapped with kindness (Kleck, Ono, & Hastorf, 1966). The motive to avoid is not socially acceptable and may not be personally acceptable either.

To test for the presence of this unacceptable motive, our general strategy calls for giving people a choice between two alternatives, one of which accidentally happens to satisfy the motive. The alternatives we used were the same as in our example above— movies.

Experiment 1

Method

Subjects

Subjects were 21 males and 4 females enrolled in Dartmouth College. They were recruited through a newspaper ad and through posters offering $2.00 to participate for half an hour in an experiment on film evaluation. One subject was deleted from the different movie condition because he knew a confederate. After the deletion there were 12 subjects in each condition.

Confederates

Confederates were three college-age males. Each session required the services of two of them, one to play the role of a handicapped person, the other to play the normal. None of the confederates were handicapped. The confederate assigned to the handicapped condition for a particular session wore a metal leg brace.

The Setting

A partition divided the wall at the far end of a large room. The furniture arrangement on one side of the partition was the mirror image of the other side. On each side was a television monitor on a table. The monitor faced out from the corner made by the partition and the wall, at about a 45° orientation from each. A few feet away, there were two chairs facing the monitor. The one closer to the partition was empty. On one side of the partition sat the normal confederate. On the other side sat the confederate with the metal brace. In addition, Canadian crutches, which are made of metal, were leaning against the table that held the monitor.

Procedure

The subject came into the room at the opposite end from the monitors and confederates, and he or she sat parallel to the far wall and in line with the partition.

Cover story. The experimenter said that he was interested in people's reactions to some comedy films from the days of silent movies. They would be watching a film and then evaluating it. To make sure the subject had a chance to notice both confederates, the experimenter left the room for approximately 60 sec, saying he had to get the film description(s).

Same movie condition. In the same movie condition, the experimenter told subjects that usually he gave people a choice between two movies but that one of the videotape machines was broken and therefore he could show only one movie. He then told the name of the movie and gave the subject a brief description of it, which he said the subject should read while he went into the next room to rewind the videotape. The experimenter returned after 2 minutes. When the subject finished reading, his attention was directed to a table located at the end of the partition. It was a small triangular table with the apex pointing toward the subject in line with the partition edge. The table was equidistant from the two confederates and from the two empty chairs. The subject was told to pick up a background questionnaire from the table, take a seat in front of either monitor, and fill out the questionnaire; the movie would begin shortly. After the movie, the real subject and the normal confederate were taken from the room, and the real subject was put in another room by himself and was asked to fill out a movie evaluation form. Then the experimenter came in, probed for suspicion, and gave a debriefing.

Different movie condition. The only difference from the same movie condition is that there was no mention of a broken videotape machine. Subjects were told that they had a choice of two movies and were given a description of each. They were told which movie was to be shown on which side of the partition. Signs taped to the edge of the table below each monitor repeated this information. They were told to sit by the monitor showing the film they would like to see. The two movies were described as follows:

> *Slapstick.* This film covers the great era of visual comedy and the clowns who made it great. Included in the film are some of the top comics of the 1920s. Charlie Chase, Monty Banks, Fatty Arbuckle, Larry Semon, Andy Clyde, and others appear.
>
> *Sad Clowns.* Charlie Chaplin, Buster Keaton, and Harry Langdon, Hollywood's comedy greats, all had widely differing styles and techniques, but a common ability to mix laughter and tears.

The following were counterbalanced: which movie was associated with the handicapped person, which side of the partition the handicapped person was on, which confederate was handicapped. The experimenter was blind as to which side of the partition the handicapped person was on. The confederates' behavior prior to the subject's choice of which side to sit on was standardized. Neither confederate looked up. Each appeared preoccupied with the background questionnaire.

Results

The first two columns of Table 1 present the choice data for the first experiment. In the same movie condition, 58% of the subjects sat with the handicapped confederate. In the different movie condition, however, in which subjects have an excuse for avoidance,

Table 1
Seating Choices

Choice	Experiment 1		Experiment 2		
	Same movie	Different movie	Same movie	Different movie	Social comparison
Handicapped	7	2	11	6	5
Normal	5	10	1	6	7

only 17% sat with the handicapped. Thus, as predicted, there is greater avoidance of the handicapped in the different movie condition than in the same movie condition. This difference between conditions is significant, $\chi^2(1) = 4.44$, $p < .05$.

For purposes of assessing alternative explanations, it is useful to ask for each condition whether results differ from the 50–50 split one would expect by chance. In the same movie condition, the slight preference for the handicapped person (58%) does not differ from the null hypothesis of 50%, $\chi^2(1) = 0.33$, *ns*. In the different movie condition, however, the 83% who chose the normal person and avoided the handicapped person is significantly greater than chance, $\chi^2(1) = 5.33$, $p < .05$. This pattern permits an alternative interpretation of the results in terms of social comparison (Festinger, 1954). The argument is as follows: In the same movie condition the subjects choose seats at random; in the different movie condition subjects believe that the two confederates have exercised a choice between the two movies. Because social comparison tendencies are stronger with a similar, that is, normal, other than with a dissimilar other, subjects are more influenced by the normal's choice. Thus, rather than avoiding the handicapped person, the subject is choosing a movie he believes to be superior on the basis of its selection by the normal. To test this explanation, we ran a second experiment, repeating the two original conditions, adding a third condition, and making a few other changes.

Experiment 2

Method

The physical setting was maintained for the tw old conditions, but the new condition involved so modifications. Two partitions were used to divi the far wall into three sections, each with a tel vision monitor. The two outer sections were occupie one by the handicapped confederate, the other b the normal. Signs were tacked to the partitions i indicate which movie each was going to see; th were never going to see the same movie. The midd section was always left for the subject. There we two additional signs on the table in front of th subject, and he was told to take the sign with th title of the movie he wished to see and place it o top of the middle TV monitor and sit down. In th condition, there is never any possibility of sittin next to the handicapped person, and there is n choice of seat, only a choice of movie. Avoidanc of the handicapped, therefore, cannot be a motiv for movie choice. Although it makes no sense to loo for avoidance in this condition, it does make sens to look for social comparison processes; that is, i the social comparison explanation for the results o the first experiment is correct, we would expect subjects to prefer the movie chosen by the normal Because the new condition required a differen physical setup in the same room, to run the study efficiently and orderly without doing great violenc to assumptions of random assignment, we alternated running first four subjects in the original arrange ment (the same and different movie conditions) and then two in the new social comparison condition Within each physical setup, the various counter balanced conditions were run in truly random fashion. And of course, within the original setup assignment to the same or different conditions was also random.

Besides the new condition, there were some addi tional changes. Subjects were again Dartmouth under graduates, 25 males and 14 females, but this time they were recruited from introductory psychology and were given extra credit for participation instead of money. Three subjects were eliminated: a female in the same movie condition who was a friend of the experimenter of the first study and had dis cussed it with him; a male in the different movie condition who was suspicious of the confederates; and a female in the different movie condition who was so preoccupied with a book that she read it whenever she could—even during the movie—and consequently never noticed the handicap. The con federates were two female students enrolled in a local high school. When the subject appeared, each confederate briefly looked up and then returned to working on the questionnaire. This time the ques tionnaire contained the Nowlis (1965) Mood Adjec tive Checklist (MACL). The MACL was given again after the movie, along with an evaluation form. The rationale for giving the MACL was that mood may be related to how people react to comedy.

Results

The third and fourth columns of Table 1 present the choice results for the second experiment. As in the first experiment, a comparison of the two original conditions shows fewer people choosing to sit next to the handicapped person in the different movie condition (50%) than in the same movie condition (92%), $\chi^2(1) = 5.04$, $p < .05$. Again, there is greater avoidance of the handicapped when there is an excuse for doing so. The manipulation of number of movies, that is, noncommon effects or plausible causes, affects avoidance in the same way as in the first study and to the same extent. In the second study, for some reason, across these two conditions people more often chose the handicapped person than they did in the first study, $\chi^2(1) = 5.37$, $p < .05$. This could be the result of a variety of factors, such as different subjects, female confederates, younger confederates.

An interesting possibility is that the confederates' looking up briefly when the subject arrived resulted in a more frequent choice of the handicapped. An explanation is available in terms of self-awareness theory (Wicklund, 1975). Self-awareness is enhanced by directing attention to self using mirrors, videotapes, audiences, and so forth. It seems plausible that eye contact enhances self-awareness. One of the consequences of self-awareness is greater conformity to salient standards. In this case the standard is probably being kind to the handicapped (Kleck et al., 1966), which is accomplished by sitting next to him or her. In this way eye contact may have led to greater affiliation with the handicapped. Snyder, Grether, and Keller (1974) report data consistent with this line of reasoning, which they interpret in a similar way. They found that hitchhikers could improve their chances of getting a ride by staring at approaching drivers.

Whatever the explanation may be, the difference between experiments is useful. The second experiment shows a significant preference for the handicapped person in the same movie condition, $\chi^2(1) = 8.33$, $p < .01$. And together, the two experiments show that the movie choice variation has the same effect at different places on the scale of net tendencies to approach or avoid the handicapped.

Now let us turn to the new condition, in which avoidance is irrelevant because the subject has no choice of seats but in which social comparison effects are possible. If in the different movie condition people sit with the normal not in order to avoid the handicapped but rather to see the movie that they believe the normal selected, they should prefer the movie the normal selected in this new condition. There is only a slight preference for the normal's movie. Seven subjects rather than the six expected by chance choose the normal's movie and this result is, of course, well within the range of chance expectation, $\chi^2(1) = 0.33$, *ns*. There does not seem to be a social comparison effect. This is not too surprising if we keep in mind that the normal confederate was a high school student discriminably younger and therefore different from the subject. Further evidence against a social comparison explanation of the main results is the significant preference for the handicapped person in the same movie condition. Every subject but one did so. Social comparison theory would suggest that a more similar other, that is, the normal, would be preferred to inform the subject as to the appropriate response to the movie. Finally, although the *ns* are too small for formal analysis, social comparison theory suggests that the results should be stronger for subjects who are the same sex as the confederates (Zanna, Goethals, & Hill, 1975). If anything, the results tended slightly in the other direction: a little stronger for females in the first study when the confederates were male and a little stronger for males in the second study when the confederates were female. In short, there were no obvious consistent sex differences, and certainly none that would suggest a social comparison explanation.

Movie Evaluation

For both experiments subjects evaluated the movie they saw on an eight-item rating form. Each item was a 7-point scale with an adjective at each end. The adjective pairs were: bad/good, weak/strong, passive/active,

Table 2
Movie Evaluation

Choice	Experiment 1		Experiment 2		
	Same movie	Different movie	Same movie	Different movie	Social comparison
Handicapped					
M	40.3	30.0	29.7	38.8	33.9
n	7	2	11	6	5
Normal					
M	34.0	38.6	38.0	34.0	32.7
n	5	10	1	6	7
Combined					
M	37.2	37.7	31.2	36.4	33.3
n	12	12	12	12	12

not at all humorous/humorous, uninteresting/interesting, frivolous/thoughtful, boring/exciting, and unimportant/important. The second adjective in each pair defined the high end of the scale. A single score was derived by summing across the eight adjectives.

Table 2 presents the move evaluation results for both experiments. We thought that evaluations might be high in the different movie condition, as subjects who avoided the handicapped person may deny that they did so by emphasizing that their decision was based on the desirability of the movie. Similarly, those in this condition who sit with the handicapped person may wish to deny that the handicap made a difference, and thus they may also stress the desirability of the movie. In Experiment 1, the average movie rating is slightly and nonsignificantly higher in the different movie condition, $t(22) = .15$. In the second experiment, compared to subjects in the same movie condition, different movie condition subjects do rate the movie more highly, $t(33) = 2.08$, $p < .05$. However, this comparison fails to control for self-selection and dissonance reduction with respect to the movie choice in the different movie condition. To control for these processes, we need to use the social comparison condition as a baseline. When we do so, results are in the same direction but short of significance, $t(33) = 1.37$, $p < .18$. The overall F for the evaluation data is also short of significance, $F(2, 33) = 2.23$, $p < .12$.

Any semblance of order in the movie evaluation data breaks down when we separate subjects according to their movie or seat choice (see Table 2). In retrospect, processes of dissonance reduction, self-selection, and justification of avoidance of the handicapped may have been joined by the additional factors of arousal about being seated next to a handicapped person, the ease of making a decision, and confederate sex to create noise. We are not inclined to offer a precise interpretation of the movie evaluation data.

In both studies, the experimenter talked with the subject about the reasons for choosing a movie or a seat. This was done sufficiently systematically in the second study to report the following: In the same movie condition, of the 11 who sat with the handicapped person, 3 mentioned the handicap in their explanation, for example, 1 said "because people usually avoid them" and 2 said "because they did not want to avoid the brace." One indicated a preference for blondes. Another mentioned a preference for the right side and added that there was no particular reason. The other 5 gave only the latter reason, or rather nonreason, as did the 1 subject who chose the normal. They said such things as "it was random," "no reason," or "I just chose."

In the different movie condition, as expected, most justified their decision on the basis of a movie preference: five of six who sat with the handicapped confederate and also five of six who sat with the normal. One who sat with the handicapped said there was no reason. One who sat with the normal said he chose by a mental coin toss.

In the social comparison condition, of the five choosing the handicapped person's film, two said it was a film preference, and three said they just chose. Among the seven choosing the normal's film, six said it was a film preference, one said "I just chose."

To sum up, 3 of the 11 subjects who sat with the handicapped person in the same movie condition acknowledged that the handicap played a role, but the handicap went unmentioned by the others. Subjects are not particularly willing to admit to affiliation on

the basis of a handicap and appear unwilling to admit to avoidance on that basis.

Anxiety

The anxiety measure was the sum of responses to "clutched up," "tense," "fearful," "nervous," "on edge," and "jittery." The score for each adjective could range from 0 to 3, and thus total anxiety scores could range from 0 to 18. Table 3 presents the results for both the first administration of the Mood Adjective Checklist—Score 1, which came right after the subject chose where to sit or which movie to see, and the second administration (Score 2), which came after the movie. For this measure the three conditions do not differ on Score 1, $F(2, 33) = 1.42$, $p < .26$, nor on Score 2, $F(2, 33) = 1.59$, $p = .22$. However, within the different movie condition, subjects who sat with the handicapped person reported more anxiety right after the choice (Score 1) than did those who sat with the normal, $t(10) = 3.18$, $p < .01$. If this occurred simply because being with the handicapped raises anxiety, we would expect similarly high levels of anxiety (Score 1) for the 11 subjects in the same movie condition who sat with the handicapped. For these subjects, anxiety levels are lower, almost significantly so, $t(15) = 1.92$, $p < .08$. Another finding of interest is the high level of anxiety among subjects in the social comparison condition who chose the normal's movie compared to those in the different movie condition who did so; for Score 1, $t(11) = 3.24$, $p < .01$. For Score 2, $t(11) = 1.13$, ns.

To summarize the anxiety results, experimental conditions by themselves have no significant effect on either score. However, both those in the different movie condition who sat next to the handicapped and those in the social comparison condition who chose the movie apparently selected by the normal scored relatively high on anxiety, significantly higher than the zero level of anxiety displayed by those in the different movie condition who sat with the normal. By the time the movie was over, however, these differences were no longer significant, largely because the two high anxious subgroups become less anxious. The decline in anxiety is not significant for social comparison subjects who chose the normal's movie, $t(6) = 1.58$, $p < .17$. It is significant for different movie subjects who sat next to the handicapped person, $t(5) = 3.24$, $p < .03$.

Table 3
Experiment 2: Anxiety Scores

Choice	Same movie	Different movie	Social comparison
Handicapped			
Score 1	2.36	5.50	3.20
Score 2	1.82	.67	2.80
n	11	6	5
Normal			
Score 1	0.00	0.00	5.57
Score 2	0.00	.33	2.71
n	1	6	7
Combined			
Score 1	2.17	2.75	4.58
Score 2	1.67	.50	2.75
n	12	12	12

Discussion

Our goal was to illustrate a general strategy for detecting motives that people wish to conceal. We suspected that people desire to avoid the handicapped but do not wish to admit it. In a kind of bootstrap operation, we have demonstrated the general strategy by using it to reveal this motive. The strategy is to ask people to choose between two alternatives, one of which accidentally happens to satisfy the suspected motive. In terms of attribution theory, having the decision to avoid or to affiliate with the handicapped also be a decision between two other alternatives is to add noncommon effects of the decision (Jones & Davis, 1965) or plausible causes for the decision (Kelley, 1972). Increasing noncommon effects or plausible causes creates ambiguity about the reasons for behavior. The person may act on an unacceptable motive while appearing to select on some other basis.

Concretely, we had subjects choose between sitting with a handicapped person or a normal, or choose between two movies, one of

which entailed sitting next to a handicapped person, the other of which entailed sitting next to a normal. In the latter case, we predicted greater avoidance of the handicapped because, objectively, motivation is ambiguous and avoidance of the handicapped can masquerade as a motive preference. In both experiments we found, as predicted, greater avoidance when the choice between people was also a choice between movies.

Anxiety scores immediately after the decision were high for the six subjects in the different movie condition who sat next to the handicapped person. But it is questionable whether simple proximity to the handicapped is the explanation, as the 11 subjects who sat next to the handicapped confederate in the same movie condition had much lower scores —a difference that statistically falls short of significance. Perhaps after sitting down they realize the ease with which they could have avoided the handicapped person—by choosing the other movie—and they begin to suspect that they possess some sort of morbid curiosity.

The other group with a high anxiety score right after the decision is the seven people in the social comparison group who chose the normal's movie. Our attempt at explaining this result is rather involved, and as we find it less than compelling, we will dispense with it here. Our final comment on the anxiety scores is that whatever differences exist right after the decision have washed out by the time the movie is over.

Similarly, the movie evaluation data are sufficiently complex to preclude a simple interpretation. One thing that might have happened but did not—at least not in any strikingly obvious fashion—is subjects in the different movie condition did not justify avoiding the handicapped person by rating the movie highly. But consider subjects' explanations for the choice during debriefing of the second experiment: Even though movie ratings were not high, subjects in the different movie condition said that their decision was based on a film preference. No one said it was to avoid the handicapped. There were only three people who mentioned the handicap in explaining their decision. They sat next to the handicapped person in the same movie condition and in debriefing expressed concern about not wanting to avoid the handicapped person.

These results still leave open the following question. When the subject does avoid the handicapped, who is the subject trying to fool: the handicapped person, the experimenter, or himself? If the phenomenon of rationalized avoidance occurs in the absence of the experimenter, imagine what the experience of the handicapped person may be like in a world so complex that it is much more like our different movie condition than like our same movie condition. The data suggest that the handicapped person may be repeatedly rebuffed in social encounters by people who give what may seem to them to be reasonable excuses. The handicapped person can then distill the attitudes of others toward him in the same way that we can in the current study. This casts doubt on whether people really fool the handicapped when they give an excuse for avoiding.

The handicapped are probably not the only group of people to receive such treatment. For one, Gaertner and Dovidio (1977) present data suggesting that blacks are comparably treated. They used the bystander intervention paradigm (Darley & Latané, 1968). Subjects were led to believe that a confederate was either black or white. Then it was made to appear that the confederate was in need of help because a stack of chairs had fallen on him. In addition to varying race of victim, the experimenters also varied the number of bystanders present. Either the subject was the only potential helper, or she was led to believe that she was one of three potential helpers. There was an interaction between race of victim and number of potential helpers on helping. When the subject was alone, the black was helped slightly and nonsignificantly more than the white was. When there were three potential helpers, however, the black victim was helped only half as often as the white one, a result that statistically was a healthy trend though a bit short of significance. The interpretation the authors offered for these results is that people do not want to help the black victim but will only act on

hat desire when they have an excuse such as he assumption that others had already helped r the thought that somebody else would be a better helper. We concur with this interpretation. We would argue that the three-helper condition is much like our different movie condition. It permits the person to act on an unacceptable motive because it provides other plausible causes for doing so. Once again, ambiguity about the motive behind behavior permits the person to fulfill an objectionable desire.

In using our motive detection strategy, one problem is how to select the two choice alternatives that constitute the added noncommon effects. A balance must be struck. On the one hand, if they are too trivial, they may lack plausibility as a basis for a decision. For instance, would we have gotten avoidance of the handicapped if we had had noticeably different, but only slightly different, chairs on the two sides of the room? On the other hand, if the alternatives are too important in and of themselves, they may overwhelm the motive to avoid the handicapped. If the film will last 3 hours and one is a western and the other is a satire, the person who hates westerns and loves satires may choose on the basis of a real movie preference even if the choice entails the discomfort of sitting next to the handicapped.

If motives can only be distilled across many decisions, is this strategy of any value in assessing the hidden motives of a single individual? We believe so. The problem is to get the person to make several decisions without arousing suspicion about what one is looking for. If the decisions are between several different kinds of alternatives and if they take place at several different times in several different contexts, the problem of suspicion may be overcome. Alternatively, instead of asking for several decisions, one could ask for only a few, but each might have several alternatives, only one of which satisfies the hidden motive. If we could avoid arousing suspicion, we could ask for a single decision among twenty alternatives and randomly select the one that satisfies the hidden motive. Selection of that alternative would be significant at the .05 level.

We believe that the layperson often uses informal versions of this strategy to get information without creating offense. Two women inspect the menu posted outside a French restaurant, trying to decide whether to enter. The wealthier one, suspecting that the other thinks it is too expensive but is too shy to say so, asks whether the other is more in the mood for Italian cuisine than for French. When the other replies that yes, she is more in the mood for Italian food, the first will conclude that the French restaurant was too expensive for her friend, but her friend is saved the embarrassment of admitting it. And there are times when the person with the hidden motive will make the excuse herself. For example, without prompting she may state that she is not in the mood for French cuisine. In short, the creation of causal ambiguity can smooth social interaction and permit participants to save face by providing socially acceptable rationalizations for behavior.

Several studies suggest that people who fear failure on a task will take steps to provide themselves with an excuse for failure by not trying very hard (Frankel & Snyder, 1978; Snyder, Smoller, Strenta, & Frankel, Note 1) or by ingesting a drug that they believe will inhibit performance (Berglas & Jones, 1978). Low effort and performance-inhibiting drugs are plausible causes for failure, and their presence creates ambiguity about whether failure should be attributed to them or to low ability.

We are pursuing the general theme that people create attributional ambiguity as in the studies just mentioned and take advantage of it as in the different movie condition of the current research. Here are some other possibilities under consideration. Poor performance in the laboratory by the depressed (e.g., Klein, Fencil-Morse, & Seligman, 1976) and by those who believe in external control of their fate (Hiroto, 1974) may be the result of a low effort strategy designed to create ambiguity about the reasons for failure. We have already shown this to be so for poor performance in the so-called learned helplessness paradigm. In this paradigm, subjects are first given unsolvable problems and then a

second task that can be done. Subjects perform worse on the second task than those initially given solvable problems or no problems. Working in this paradigm, we gave subjects ready-made excuses for failure on the second task by describing the task as difficult (Frankel & Snyder, 1978) or by playing music alleged to be distracting (Snyder et al., Note 1). Their performance improved, presumably because the excuse we provided allowed them to try without forcing them to blame failure on lack of ability.

We can also ask whether procrastination is sometimes a means of providing an excuse of lack of time for possible failure. Does the involvement in multiple and diverse achievement activities that characterizes the Type A or coronary-prone behavior pattern allow such a person to lay failure in a single activity to having spread himself too thin? Is social comparison with similar others avoided or obscured when one fears a negative conclusion? Is affiliation under stress sometimes a means of creating ambiguity about responsibility by diffusing it among members of a group? We think the time is ripe to explore how people exploit rational principles of attribution (e.g., correspondent inference theory, the discounting principle) to serve such needs as self-esteem and self-presentation through the creation and judicious use of attributional ambiguity.

Does Aggression Cause a Preference for Viewing Media Violence?

Allan Fenigstein
Kenyon College

Virtually all of the research concerned with media violence has attempted to determine whether the viewing of violence is associated with or causes aggression. Little experimental research has been directed at understanding why persons view media violence. The present research experimentally tested the hypotheses that physical aggression and fantasy aggression would lead to a preference for viewing violence. In Experiment 1, undergraduate men and women were induced to express aggressive, nonaggressive, or no fantasies and were then given an opportunity to select film clips for viewing. The films chosen by men contained more violence than those chosen by women. In addition, aggressive fantasies in males, compared to nonaggressive fantasies, increased the preference for viewing violence. Experiment 2, using only males, replicated the results of the first study and also found that men who were given an opportunity to aggress physically, compared to those who had no such opportunity, were more likely to choose to view films containing violent content. These results provide an additional perspective on the relationship between the observation of violence and the expression of aggression by suggesting that the causal effects are bidirectional: Just as the viewing of violence may increase aggression, so, too, aggressive behavior may increase the preference for viewing violence.

Psychologists have shown a strong interest n the relationship between the mass media nd behavior, especially with respect to ob-erved and expressed aggression. Extensive orrelational research using a number of ifferent indices of violent programming and ggressive behavior has consistently shown hat exposure to violence and antisocial be-avior are positively related (e.g., Dominick Greenberg, 1971; Lefkowitz, Eron, Walder, Huesmann, 1971; McIntyre & Teevan, 971; and McLeod, Atkin, & Chaffee, 1971). One causal explanation of this relationship hat has received considerable experimental pport has been that the observation of iolence leads to aggressive behavior. Since the early 1960s, an impressive number of laboratory and field experiments have investigated the consequences, for aggressive behavior by the observer, of observing violence (e.g., Bandura, Ross, & Ross, 1961; Berkowitz, 1965; Berkowitz & Geen, 1966; Leifer & Roberts, 1971; Liebert & Baron, 1972; Murray, 1973; Stein & Friedrich, 1971; Steuer, Applefield, & Smith, 1971). Although these experiments were conducted under several diverse theoretical frameworks such as social learning theory and drive theory, and in spite of some disconfirming evidence (e.g., Feshbach & Singer, 1971; Kaplan & Singer, 1976; and Milgram & Shotland, 1973), there is a remarkable degree of convergence in the experimental literature suggesting that the observation of violence contributes to aggression (Geen, 1976).

In view of the predominance of violence in the mass media (Baker & Ball, 1969; Clark & Blankenburg, 1971; Gerbner, 1971) and its potential for harm, it would seem important to know why persons seek out violent

Portions of this article were presented at the nnual Convention of the American Psychological ssociation, Toronto, August 1978. This research as conducted while the author was on leave at the niversity of Virginia.

material for viewing. Although research on media violence and aggression has been prolific, virtually no experimental work has been directed toward understanding the determinants of the preference for viewing violence (Kaplan & Singer, 1976; Weiss, 1969). The present studies attempt to identify some factors that may affect one's exposure to media violence. Specifically, it is proposed that aggression on the part of the viewer leads to a heightened interest in viewing violence. A number of previous studies have found individual differences in the preference for viewing violence that are consistent with this proposal (Diener & DeFour, 1978; Greenberg & Gordon, 1971). Diener and DeFour, for example, found a positive relationship for men between dispositional aggression and liking for program violence. One causal explanation for these findings is that aggressive persons seek out violent programs; presumably, aggressive thoughts or actions set in motion certain psychological processes, such as the need to understand one's behavior, which then cause persons to seek out portrayals of violence in the media.

The hypothesis that aggression is a causal antecedent of the viewing of violence may also be seen as an alternative interpretation of the well-established correlation between the observation of violence and the occurrence of aggression. As noted earlier, a causal relationship positing that the viewing of violence facilitates aggressive behavior has received considerable experimental support. This evidence, however, does not provide a complete explanation of the aggression–television relationship; a substantial portion of the variance in this relationship remains unaccounted for, and additional explanatory mechanisms are warranted (Eron, Lefkowitz, Huesmann, & Walder, 1972). Furthermore, the existence of a unidirectional causal relationship does not rule out the plausibility of a bidirectional relationship. It is quite possible that aggressive behavior would result in congruent viewing preferences, while at the same time media exposure would be shaping subsequent behaviors. Although both explanations are feasible, only one—that viewing violence increases aggression—has been systematically subjected to experimental verification. The present research contends that a better and more complete understanding of the relationship between aggression and the visual mass media can be achieved by examining the hypothesis that aggression may also increase selective exposure to filmed violence.

There are two *correlational* studies that have used statistical techniques to determine if a preference for violent TV programs is caused by aggression. Chaffee and McLeod (1973), using a systematic process analysis, found no relationship between reports of aggressive behavior and preference for televised violence. However, these investigators found only a weak correlation between their measure of preference and actual viewing of violent programs. Thus, the validity of the preference measure itself is somewhat open to question. Lefkowitz et al. (1971), using a cross-lagged panel technique, found no relationship between aggressive behavior at age 9 and the viewing of violence on TV 10 years later, again suggesting that the preference for viewing violence is not caused by prior aggression. However, this study failed to rule out any immediate effects of aggression on the preference for viewing violence, and the reliability of the measures used is also open to question (see Eysenck & Nias, 1978). In addition to the specific drawbacks of these two studies, correlational research in general cannot control all relevant variables, and the possibility of interference by third-order variables rules out any definitive conclusions regarding causal relationships. Even if the data generated by these studies were completely reliable and valid, the fact remains that *only two* studies (both correlational) exist that address the question of the effects of aggression on the preference for viewing violence, and neither of these studies has examined the problem through direct, controlled experimentation.

The first study reported here focused specifically on fantasy aggression as a causal antecedent of the preference for mass media violence. The fact that much of the violence on television is a visually presented fantasy suggests that *aggressive fantasies* may be particularly relevant to an understanding of TV

viewing preferences, and previous research has shown that the two variables are related (Feshbach, 1976). One explanation for this relationship may be found in Feshbach's (1961) work showing that watching violence on TV produced an increase in fantasy aggression. However, the present research suggests a *different causal sequence*: the presence of aggressive fantasies may lead to a preference for viewing violence. Thus, it was predicted that subjects who were induced to express an aggressive fantasy would have a greater interest in viewing violence than those expressing nonaggressive fantasies.

Experiment 1

Method

Subjects. The subjects were 45 female and 42 male undergraduates who participated as part of a course requirement in introductory psychology.

Procedure. In the context of a two-part experiment described as investigating "the effects of verbal and visual stimuli on thought processes," subjects were induced to express either an aggressive or a nonaggressive fantasy. In addition there was a group that was not given any opportunity to fantasize. All subjects were subsequently asked to select film clips for viewing. Subjects in the fantasy conditions were first presented with one of two sets of 24 words and were asked to construct a story using these words. For one group of fantasy subjects, 10 of the words on the list had aggressive connotations (e.g., hurt, insult, knife, anger); for the other group, matching nonaggressive words were used (e.g., help, praise, pen, joy). The remaining 14 words were constant for both groups (e.g., park, couple, dog, light). Instructions were to describe an event, its antecedents, and its outcome, and to describe the thoughts and feelings of the characters in the story. Subjects were given 10 minutes to construct and take notes on their stories, and then the story was tape-recorded for later analysis. The no fantasy group participated in a brief free-recall paradigm during this part of the study.

All subjects participated in the next part of the study, which was conducted by a second experimenter in a different room. Subjects were told that they would be shown a series of film clips and that subsequently certain (unspecified) cognitive processes would be examined. In this instance, subjects were to have the opportunity to select 10 films from a total pool of 26. Each clip was supposedly about 1 to 2 minutes long and was described by a brief phrase, for example, "rioting at a rock concert," "a downhill ski run," "a fist fight," "a student taking a test." Each film description had been previously rated by 14 raters, 7 men and 7 women, on three dimensions: aggression, interest, and action. There were no gender differences on the ratings, suggesting that it is unlikely that a sex bias was operating in the perception of the films. Interrater agreement was high, averaging 84.9%, indicating that the perceived aggressive content, degree of interest, and amount of action were reasonably consistent across viewers.[1] As an example, on a scale of 0 (contains none at all) to 3 (contains a great deal of), the film described by the phrase "the Mardi Gras festival" received average ratings of 1.38 on aggression, 2.61 on interest, and 2.76 on action; the film described as "a person getting hit by a brick" had average ratings of 2.90 on aggression, 0.84 on interest, and 2.15 on action. The total aggression, interest, and action scores of the 10 films chosen constituted the major dependent variables.[2]

These three dimensions were assessed in an attempt to remove, through covariance techniques, a persistent confound that pervades research on media violence: specifically, that a violent program usually contains a good deal of action and that violence often occurs in a context of other interesting story elements; thus it is difficult to measure the effect of violence alone. This confound was confirmed by pretest scores indicating that aggressive content was significantly correlated ($p < .01$) with both interest ($r = .54$) and action ($r = .81$). By measuring and statistically controlling for the amount of action and interest of each film chosen, it was possible to obtain a relatively unconfounded indication of the preference for viewing films with aggressive content.

Following the choice of films, all subjects were given a questionnaire that assessed their expectations of the films they chose. Subjects were asked to rate the chosen films, as a group, on 7-point bipolar scales measuring interest, humor, violence, action, educational value, and aesthetic value. Experimental subjects only were also given a second questionnaire, which asked them to indicate the motives (e.g., achievement, aggression, dominance, nurturance) and emotions (e.g., pleasure, fear, surprise, disgust, anger) that had been expressed in their earlier "word stories" on a scale of 1 (not expressed at all) to 5 (expressed very strongly). Finally, all subjects were debriefed.

Results

In view of the possibility of gender differences in aggression (see Maccoby & Jacklin,

[1] Interrater agreement was assessed by dichotomizing the aggression rating continuum into low aggression scores (0 & 1) and high aggression scores (2 & 3). The percentage of agreement on each film description was then calculated: for example, if 11 of the 14 raters gave a high score, then the agreement on that film was 78.57%. The percentage of agreement for each film was then used to calculate an overall mean agreement of 84.9%.

n	13	22	10
Men			
M	1.28	1.49	1.71
n	10	20	12

Note. Scores range from 0 (low aggression) to 3 (high aggression).

1974), sex was used as a variable in the analyses.

Success of the fantasy manipulation. The word-story method used in the present study had no prior validation as a technique for inducing fantasies. Thus, it was necessary to determine whether the fantasy groups differed in terms of the stories they told. When 2 (Nonaggressive, Aggressive Word-Story) × 2 (Male, Female) analyses of variance were performed on the subjects' perceptions of the motives and emotions expressed in their stories, sex had no effect, nor were there any significant interactions. However, subjects using aggressive words perceived their stories as expressing significantly more fear ($p < .004$), disgust ($p < .002$), anger ($p < .001$), and hatred ($p < .001$), and significantly less pleasure ($p < .004$), happiness ($p < .001$) and love ($p < .04$) than those using nonaggressive words. Similarly, aggressive-word subjects felt their stories had indicated greater needs for aggression ($p < .001$) and dominance ($p < .001$) and lesser needs for nurturance ($p < .01$) and affiliation ($p < .02$) than the nonaggressive-word subjects.

In addition, preliminary content analyses of the fantasies leave little doubt that the word-story technique is a successful means of inducing specific fantasies. In view of this success, it may be well to point out that this method is considerably easier to administer and score and, perhaps more important, may offer greater experimental control over the nature of the fantasy induced, than other well established fantasy instruments such as the Thematic Apperception Test (TAT).

Aggressive content of chosen films. The total aggression scores of the 10 films chosen is presented in Table 1. A 3 (Aggressive, Nonaggressive, or No Word-Story) × 2 (Male, Female) analysis of variance on these scores revealed a main effect for sex, $F(1, 81) = 39.5$, $p < .001$, and a significant Sex × Fantasy interaction, $F(2, 81) = 6.6$, $p < .002$. Films chosen by men contained significantly more aggression than those chosen by women. Planned comparisons showed that when induced to express aggressive fantasies, men had a far stronger preference for observing violence than women, $t(20) = 5.56$, $p < .001$. Also, in the absence of any induced fantasy, men were more likely than women to prefer films containing violence, $t(40) = 4.49$, $p < .001$.

Of more interest to the hypotheses of the present study is the finding that aggressive fantasies, compared to nonaggressive fantasies, increased the amount of violence in the films chosen by males, $t(20) = 4.0$, $p < .001$, but had no effect on the violent content of films chosen by women.

Interest and action levels of chosen films. The films chosen by males contained more action, $F(1, 81) = 16.2$, $p < .001$, and were more interesting, $F(1, 82) = 5.37$, $p < .03$, than those chosen by women. However, these preferences for action and interest in films chosen were not affected by the type of fantasy induced, nor were there any significant interactions between the sex and fantasy variables on these dimensions.

Covariation. In view of both the sex effects for action and interest content of the films and the previously reported intercorrelations between aggression, interest, and action content of the films, a 3 × 2 covariance analysis was performed on the total aggression scores of the films chosen, using action and interest scores as covariables. This analysis yielded a significant effect for sex, $F(1, 79) = 8.00$, $p < .006$, and a significant Sex × Fantasy interaction, $F(2, 79) = 5.38$, $p < .008$, suggesting that the preferences for violent film content operate independently of the films' action and interest content.

Discussion

Gender effects. It may be argued that aggression in contemporary society is essentially a masculine behavior, and the present study found that this gender difference apparently generalizes to film preferences. Several reasons for this difference may be suggested. Socialization strongly affects the expression and acceptability of aggression (Bandura, 1973), resulting in a greater frequency of physically aggressive acts on the part of males than females. This increased familiarity with and exposure to aggressive scenes may heighten the attractiveness of aggressive stimuli (Zajonc, 1968). Men's preferences for viewing violence may also be partially understood in terms of the appropriateness of the role models and behavior patterns displayed in such media presentations. Given these socialization expectations, the results of the present study may be offered in partial support of the validity of the film preference measure.

The sex differences that emerged in this study may also be used to address the issue of demand characteristics. It may be argued that the words given to the aggressive fantasy group provided cues as to the major hypothesis of the study. But since there was no evidence that these cues led to differences in the aggressive content of the stories told by men and women, it is unlikely that these same cues could account for the subsequent gender differences in the violent content of the films chosen. That is, a demand characteristics interpretation cannot explain why men and women responded differently in one part of the experiment, but not in another, to the supposed demand cues.

In addition, the debriefing sessions yielded little indication of suspicion. The cover story proved to be effective in that very few subjects made any explicit connection between the fantasy part of the experiment and the film choices. No mention was ever made of the aggressive nature of the word stimuli, and fantasy subjects invariably perceived their stories as being of their own creation. Finally, accurate knowledge of the hypothesis under investigation was never spontaneously offered by any subject. Thus, there is no evidence to support a strong demand effect.

In view of some recent evidence suggesting that sex differences in aggression are decreasing (see Baron, 1977), the finding that preferences for viewing violence was stronger for men than for women may be considered somewhat puzzling. It should be noted, however, that the experimental research showing a decline in sex differences deals primarily with angry aggressive behavior, whereas the present research is concerned with aesthetic preferences for viewing violence; thus it may be that sex differences are diminishing in the domain of instrumental behavior but continue to exist in the area of expressive behavior. In response to these issues, additional data was gathered (as part of another experiment unrelated to the present hypotheses) on the viewing preferences of 21 women and 20 men, assessed with the same measures used in the first study. The gender differences of Experiment 1 were clearly replicated: The films that men chose to view contained more violence than those chosen by women, $F(1, 37) = 50.9$, $p < .001$, again providing evidence for the existence of sex differences in the preference for viewing violence.

Fantasy effects. The present findings support the hypothesis that the expression of aggressive, compared to nonaggressive, thoughts and images would result in corresponding viewing preferences, but this was the case only for men. For women, the degree of preference for violent films was relatively constant across all conditions, and generally lower than men's preferences; this may best be attributed to socialization pressures that produce a consistent indifference or antipathy on the part of women toward violence in the media.

It is clear that men's film preferences were affected by the nature of their preceding fantasy, but the underlying mechanisms are open to speculation. Singer (1966) has shown that the expression of specific fantasies may arouse corresponding motives. Thus, subjects in the aggressive fantasy condition, compared to those in the nonaggressive fantasy condition, may have experienced a heightened motivation toward aggression. It may be argued

that persons who are motivated to aggress show an increased preference for violent media programs under several different circumstances: Given that the observation of violence facilitates aggressive behavior (Geen, 1976), a person in a prepotent state of aggression may seek out media violence; and if there is no expectation or opportunity for aggression, then media violence may be sought out for its symbolic catharsis value (Geen, 1976), as a means of vicariously satisfying the aggressive drive (Pytkowicz, Wagner, & Sarason, 1967; Rosenbaum & DeCharms, 1960).

Alternatively, the underlying explanation may involve cognitive rather than behavioral processes: Fantasy aggression may lead to increased exposure to violent stimuli for purposes of social comparison (Festinger, 1954). That is, one may wish to compare his own visual image of an aggressive event with that provided by the media. Clearly further research is needed to identify the nature of the processes that underlie the relationship between aggressive fantasies and exposure to media violence. But despite the absence of any clear explanatory mechanisms, the significance of the basic phenomenon should not be overlooked: Aggressive fantasies in males have been shown to increase their preference for viewing violence. Thus, an important antecedent of the preference for viewing violence has been uncovered. In addition, the relationship between TV violence and aggression may be viewed from a new perspective: Not only does television violence increase aggressive behavior, but aggression, in the form of fantasies, also leads to a heightened preference for filmed violence.

Experiment 2

The results of the first study left unanswered the question of whether the tendency to observe violence is affected by overt aggressive *behavior*. Earlier correlational studies demonstrating a relationship between observed violence and aggression were concerned specifically with behavioral measures of aggression (e.g., Dominick & Greenberg, 1971; McIntyre & Teevan, 1971). As suggested earlier, a reasonable explanation for this relationship is that aggressive behavior increases the preference for viewing violence. Several mediating processes may be proposed. Persons who behave aggressively may selectively expose themselves to media violence because of a *need to justify* their prior behavior (Aronson, 1976; Brock & Buss, 1962; Glass, 1964). Watching others act aggressively may provide that justification by intimating that aggression is an appropriate, acceptable behavior (Bandura, 1973; Geen, 1976). In addition, aggression may arouse the need to understand one's aggressive behavior, and that need may be satisfied through *social comparison* processes (Festinger, 1954), leading to the observation of other's aggressive behavior on film. In this context, it is interesting to note that exposure to sexually explicit stimuli is also believed to be a function of social comparison needs; that is, it provides a way of comparing ourselves with others (Byrne, 1976).

Thus, the second study hypothesized that physical aggression would increase the preference for viewing violent film stimuli. Fantasy aggression was also included as a variable in this study because of the desirability of replicating the findings of Experiment 1.

Method

Subjects. The subjects were 64 male undergraduates who participated as part of a course requirement in introductory psychology.

Overview. There were three parts to the study. Subjects first had the opportunity to express either an aggressive or nonaggressive fantasy; a third group did not undergo the fantasy induction. In the second part, half the subjects delivered supposedly painful noises to another person; the other subjects did not use noises. Finally, all subjects indicated their film preferences.

Procedure. Prior to the experiment, informed consent concerning the use of noise was obtained from all subjects, and they were informed of their right to withdraw at any time without penalty. Subjects were scheduled individually and participated with another male subject (actually a confederate). The experiment was described as being interested in the effects of "verbal, visual, and evaluative stimuli on thought processes." It was explained that the participants would work together in some parts of the experiment and separately in other parts. The

st part involved individual participation, and the bject was asked to remain in the room while the nfederate was sent elsewhere. This part of the periment was described to the subject as examin- g the "effects of verbal stimuli on thought pro- esses," and was intended to induce aggressive and onaggressive fantasies, using the same word-story ntasy induction technique as in Experiment 1. gain, subjects were divided into (a) an aggressive ord group, (b) a nonaggressive word group, and c) a no fantasy group that participated in a brief ow-recall paradigm during this part of the study.

After completing the first part, all subjects were ent to a second room, where another experimenter blind to the subjects' fantasy condition) conducted he next part of the study. During this time, the ubject and confederate participated together. For ubjects in the aggression condition, this portion of the experiment was described as looking at how "evaluative feedback in the form of unpleasant oises affects creative thinking ability." Subjects were supposedly to deliver noxious noises to the confed- rate as a means of evaluating the creativity of his esponses in a free-association task (cf. Konečni, 975). The subject read from a list of words, and the nfederate was expected to give a "one word esponse that is as creative as possible." It was explained that it was completely up to the subject o "decide how creative each response is." This was o be communicated through the use of 10 buttons n a Buss (1961) type aggression apparatus that an deliver 10 different levels of "static noise" to he confederate through earphones. The subject was o provide one evaluation for each response. If the nfederate's response was not creative, the subject would indicate that by giving a high level of noise; f the response was very creative, a low level of oise would be chosen. The subject was reminded hat although the noises may be "painful, they are ompletely controlled and are in no way dangerous." (Of course, no noises were actually used.)

The subject was then told that "we have a reason- able understanding of the effects of very high and very low levels of noise, so what would be of most value now would be to examine the effects of moderate noise levels, say Buttons 4 through 7. Although this restricts the range of your evaluations to some degree, you still have the freedom to use any button in that intermediate range." (It must be emphasized that in this study aggression was not a dependent variable, but rather an independent variable. The experiment was not interested in mea- suring aggression; rather it was attempting to *control* aggressive behavior. By manipulating the subjects' range of responses, it was insured that all subjects in this condition would believe that they were de- livering a moderate amount of noxious stimulation to another and thus would be acting aggressively [Buss, 1961]. Pilot work had indicated that these instructions were successful in controlling the sub- jects' aggressive responses to an average noise level of about 5).

Subjects in the no aggression condition were told that this second part of the experiment examined how "another's evaluation affects creative thinking ability." They were given essentially the same in- structions concerning the evaluation of the confed- erates' creative responses and used the same apparatus as aggression subjects did, but control subjects were told that their evaluations were indicated on the confederate's light panel that corresponded to the subject's button panel. Confederates in this case did not wear earphones, and there was no mention of the use of noise. As before, subjects were informed that Button 1 indicated a highly creative response and Button 10 a noncreative response. Again, it was explained that the experiment was interested in moderate (4 to 7) levels of evaluation. In both condi- tions, confederates surreptitiously recorded the levels used by the subject, and the experimenter briefly questioned each subject concerning his per- ception of the button's effects. This information was again elicited during the final debriefing session. In all cases, subjects in the noise condition indicated awareness of the aversiveness of their responses, whereas no such information was offered by subjects in the no noise condition.

After the second part of the study had been com- pleted, the subject alone was sent to a third experi- menter, who was blind as to the subject's experi- mental condition. As in Experiment 1, the subject was told that this part of the study was interested in the "effects of visual stimuli on thought pro- cesses." The procedure for choice of films used in the first study was followed here. Following the choice of films, all subjects filled out questionnaires assessing their expectations of the chosen films, and exerimental subjects also indicated the motives and emotions expressed in their fantasies. After completion of the experiment, participants were fully debriefed. Again, there was little indication of suspicion, and no subject was able accurately to ascertain the actual hypothesis of the study.

Results

Fantasy manipulation. The success of the fantasy induction was determined by perform- ing 2 (Nonaggressive, Aggressive Word-Story) × 2 (No Noise, Noise) analyses of variance on the subjects' perceptions of the motives and emotions expressed in their stories. The noise variable had no effect, and there were no significant meaningful inter- actions. There were strong effects, however, for the word-story manipulation, and these were virtually identical with the results of the first study. Subjects using aggressive words perceived their stories as expressing signifi- cantly more fear ($p < .004$), disgust ($p < .001$), anger ($p < .001$), and hatred ($p < .001$), and significantly less pleasure ($p <$

Table 2
Mean Aggression Scores of Films Chosen

Stimulus	Fantasy condition: Non-aggressive	None	Aggressive
No noise			
M	1.28	1.41	1.48
n	12	8	12
Noise			
M	1.63	1.78	1.80
n	12	8	12

Note. Scores range from 0 (low aggression) to 3 (high aggression).

.001), happiness, ($p < .001$) and love ($p < .001$). Again, subjects in the aggressive fantasy condition felt that their stories had indicated greater needs for aggression ($p < .001$) and dominance ($p < .001$) and lesser needs for nurturance ($p < .001$) and affiliation ($p < .002$) than subjects in the nonaggressive fantasy condition believed their stories had shown. Thus, the success of the fantasy manipulation was well established.

Film preferences. The major dependent variable was the total aggression scores of the films chosen (see Table 2). A 3 (Aggressive, Nonaggressive, or No Word-Story) × 2 (No Noise, Noise) analysis of variance yielded an effect for noise, $F(1, 58) = 21.0$, $p < .001$, and a marginally significant main effect for fantasy, $F(2, 58) = 2.46$, $p < .10$; there was no interaction between the aggression and fantasy variables on this measure. Subjects who had had an opportunity to aggress physically using noise clearly had a stronger preference for viewing violent films than did subjects who had no opportunity to aggress; planned comparisons showed that this effect was consistently significant across all fantasy conditions.

To assess the effects of the fantasies on film preferences more clearly, an additional analysis of variance was performed involving only those groups that had expressed fantasies. This analysis indicated that there was a greater preference for viewing violence among the aggressive fantasy subjects than among the nonaggressive fantasy subjects, $F(1, 44) = 4.18$, $p < .05$. Planned comparisons found that in the no noise condition (which is comparable to Experiment 1), there was a greater amount of violence in the films chosen by men who expressed an aggressive fantasy than in the films selected by those in the nonaggressive fantasy condition, $t(22) = 1.91$, $p < .05$.

Covariance analyses. Films chosen by subjects who had physically aggressed involved more action, $F(1, 58) = 15.4$, $p < .001$, and were more interesting, $F(1, 58) = 6.53$, $p < .02$, than did those chosen by the nonaggression group. Fantasy had no effect on preferences for action or interest, nor were there any interactions. These aggression effects suggested the need for a 3 × 2 covariance analysis, using interest and action scores as the covariates, in order to determine whether preferences for viewing violent films were independent of the films' action and interest content. The results of the analysis indicated that this was the case: There was now a significant effect for fantasy, $F(2, 56) = 3.26$, $p < .05$, as well as an effect for physical aggression, $F(1, 56) = 5.70$, $p < .02$.

General Discussion

Empirical Findings

It was hypothesized that both physical aggression and fantasy aggression would lead to an increased preference for viewing violence. These predictions were confirmed for men. Experiment 2 effectively replicated the first study: Both found that for males, the expression of an aggressive fantasy, compared to a nonaggressive fantasy, led to a greater preference for viewing violence. In the second study, this effect was sustained despite the fact that another time-consuming and impactful manipulation interceded between the fantasy condition and the dependent measure. Experiment 2 also found that persons who physically aggressed toward another, using noxious noise, were far more likely to choose to view violence than were those who had not aggressed.

Although the present studies represent the first experimental demonstration that aggressive behavior leads to the viewing of violence,

his causal hypothesis is completely consistent with previous correlational work demonstrating a positive relationship between TV violence and aggression. Several other studies, conducted in both the laboratory and the field, may also be interpreted in terms of the major hypotheses of the present research. Doob and Macdonald (1979) found that people in high crime areas watched more violent TV than those in low crime areas. Similarly, Boyanowsky, Newtson, and Walster (1974) found that attendance at a violent movie increased markedly following a brutal local murder, whereas no such increase in attendance occurred for a nonviolent film. A possible explanation for both these findings is that violent crime results in a heightened preoccupation with aggressive thoughts and fantasies, which then leads persons to seek out violence in the media. Feshbach, Stiles, and Bitter (1967) showed that witnessing acts of aggression may have reinforcing effects, but only for those who have been insulted. Again, this is consistent with the notion that persons seek out media portrayals of violence following an episode in which they experienced aggressive thoughts or feelings. Finally, it has been reported that low-income and black youths enjoy watching filmed violence more than middle-class youths do (Greenberg & Gordon, 1971); and dispositionally aggressive men have a greater preference for viewing violence than do those who are nonaggressive (Diener & DeFour, 1978). Presumably, aggression in one's own life results in congruent viewing preferences. Taken together with the present research, these studies provide considerable evidence for a theory of viewer behavior: Persons watch violence in the media because of both long-term and situationally induced aggressive thoughts and actions.

Implications

The problem of violence in the mass media has attracted a great deal of public, governmental, and scientific attention. That attention has been primarily focused on the *consequences* of viewing violence in the mass media, with little research having been directed toward the *antecedents* of the viewing of violence. Yet, in a sense, the two are inseparable: in order to understand the effects of the mass media, it is necessary to understand why viewers watch the media; and conversely, to understand viewing behavior, the effects of the mass media must be known. Cognizant of the fact that watching violence facilitated aggression, the present research assumed that aggression, both physical and fantasy, was related to the viewing of violence. The results suggest that the assumptions were warranted: The preference for watching violence may be attributed, in part, to aggression-related behaviors on the part of the viewer.

The present research also provides an additional perspective on the relationship between the observation of violence and the expression of aggression: aggressive behaviors and fantasies are not only a *result* of viewing violence, as established by previous research (e.g., Eron, et al., 1972; Feshbach, 1961), but may also be a *cause* of the viewing of violence. Just as what one watches in the media influences one's behavior, so too the way one behaves influences what one watches. This bidirectional model of influence argues for a cyclical pattern of effects such that aggressive thoughts and actions increase one's preference for viewing violence in the mass media, which in turn increases aggressive behavior.

Finally, the research helps to counter some of the criticism that has been directed at the form of mass media research. Because previous experimental research on television violence and aggression was interested in the effects of watching violence, the typical research paradigm denied the participant the *choice* of what to watch; subjects were simply exposed to predetermined programs, and effects were measured. This procedure, although standard (e.g., Friedrich & Stein, 1973; Liebert & Baron, 1972), may be considered ecologically invalid in that it disregards tendencies or motives that may determine the choice of program and may interact with the program content in affecting subsequent behavior. The present research partially overcomes these criticisms by investigating and identifying some of the variables

that affect what the viewer selects to watch, thus directing attention to the reciprocal nature of the relationship between aggressive behavior and mass media violence.

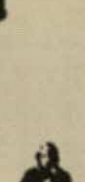
GRADUATE STUDY IN PSYCHOLOGY 1980-1981

Prospective psychology graduate students and college counselors will find *Graduate Study in Psychology for 1980-1981* an indispensable resource. This 13th annual edition published by the American Psychological Association provides 656 pages of up-to-date, specific information on more than 550 graduate programs in the United States and Canada. Listed for each institution are application procedures, admission requirements, tuition, financial assistance, internships, and minority considerations. General information on applying to graduate school is included to help with that important decision about graduate study. Price: $7.



To order, write to:

New Directions in Psychology

PERSONALITY THEORIES, *Fourth Edition*

Salvatore Maddi, *University of Chicago*

This thoroughly absorbing text compares and contrasts many theoretical viewpoints with a comprehensive, consistent, and original framework for the personality field. Pertinent issues are posed and research studies are examined for their value in resolving issues. **Teacher's Manual.** 1980

UNDERSTANDING SOCIAL PSYCHOLOGY, *Revised Edition*

Stephen Worchel, *University of Virginia* and
Joel Cooper, *Princeton University*

The traditional areas of social psychology are covered in both theory and research along with demonstrations of how social psychology can and cannot be used to understand "real world" incidents. Includes a new chapter on socialization. **Student Study Guide. Teacher's Manual.** 1979

PERSONALITY: Strategies and Issues, *Third Edition*

Robert M. Liebert, *State University of New York at Stony Brook* and
Michael D. Spiegler, *Providence College*

Widely respected and highly readable introduction to major strategies and issues in the psychological study of personality. New discussions of attribution theory and cognitive behavior modifications are included. **Instructor's Manual.** 1978

Examination copies for adoption consideration available on request. Please indicate course title and text presently used.

Nebraska Symposium on Motivation, 1978
Human Emotion

Edited by
Herbert E. Howe, Jr., and Richard A. Dienstbier

With this volume of the Nebraska Symposium on Motivation, the concept of motivation regains some of the importance that it held in the inception of the series. The authors study the interrelationship between motivation and emotion from various theoretical standpoints, utilizing a wide variety of research data to support their views. Includes "Anger" by James R. Averill, "Behavior Analysis of Motivational and Emotional Interactions in a Programmed Environment" by Joseph V. Brady and Henry H. Emurian, "Psychoneuroendocrine Approaches to the Study of Emotion as Related to Stress and Coping" by Marianne Frankenhaeuser, "Emotions as Motivations: An Evolutionary-Developmental Perspective" by C. E. Izard, "Script Theory: Differential Magnification of Affects" by Sylvan Tomkins, and "Emotion-Attribution Theory: Establishing Roots and Exploring Future Perspectives" by Richard A. Dienstbier.

xxvi, 321 pages.

Cloth **$17.95**
Paper **$ 8.95**

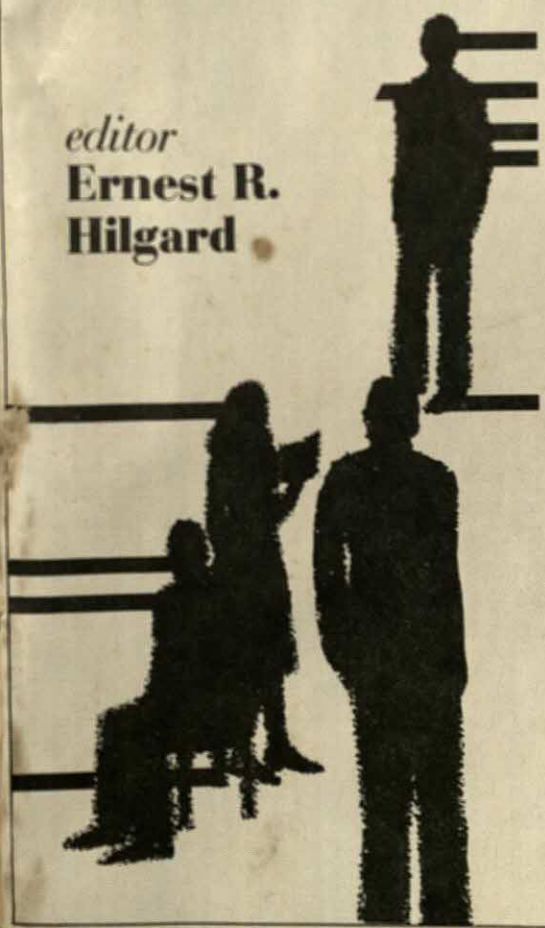
American Psychology in Historical Perspective

1892-1977

editor
Ernest R. Hilgard



Now available in one book — 21 APA presidential addresses in their entirety from some of the most important names in American psychology. Included are classic pieces from James, Cattell, Dewey, Thorndike, Woodworth, and Watson. You'll also find Harlow's "The Nature of Love" and Miller's "Analytical Studies of Drive and Reward."

This book is truly a milestone for historical psychology. It provides both a fascinating chronology of the presidents of the American Psychological Association from 1892 to 1977 and a valuable collection of significant essays.

This new APA publication traces the development of American psychology over four broad periods in psychology's history: the first 25 years (1892-1916), the years of the two world wars (1917-1945), the 20 years after World War II (1946-1967), and the recent past (1968-1977).

For each of these periods, the editor, Ernest R. Hilgard, provides a brief summary of the thinking in psychology at the time, biographies of all the APA presidents with abstracts of their presidential addresses, and the selected presidential addresses in full.

American Psychology in Historical Perspective *may be ordered in hard cover for $18 or in soft cover for $15 by writing to: American Psychological Association, Order Dept., 1200 Seventeenth Street, NW, Washington, D.C. 20036*

Please include full remittance for orders of $25 or less.

The Psychology Major

Training and Employment Strategies

By **Paul J. Woods,** 1979, 384 pages, 6⅛" x 9¼". Price: $10.

Faced with an increasingly competitive job market, students and faculty alike will find *The Psychology Major* invaluable in the selection of courses, work, and field experience that employers seek.

Contributions are presented in four sections. "Preparation and Strategies for Employment" consists of "how-to-do-it" chapters of guidance and advice for those at the undergraduate level. The next section discusses "Job Prospects: Potential and Real."

The psychology graduate's role and job prospects in community agencies and paraprofessional positions is examined separately in "Training for Careers in Community Services, Mental Health, and Public Affairs." The last section, "The Undergraduate Major: Surveys, Models, and Problems" provides overviews of existing programs (including practica, field work, and internships) and areas of innovations and resistance to change in undergraduate training.

In the appendixes, the author presents valuable training and employment strategies such as an annotated bibliography on curriculum and careers, U.S. Civil Service Qualifications Standards for psychological jobs, a listing of Federal Job Information Centers and state personnel offices, and a description of strategies for admission.

This latest work from Paul J. Woods serves as a companion to his earlier *Career Opportunities for Psychologists* (APA, 1976).

To order, write to: American Psychological Association, Order Dept. • 1200 Seventeenth Street, NW Washington, D.C. 20036

Orders of $25 or less must be prepaid.
